Supernumerary tracheal bronchus supplying a segment of pulmonary tissue known as the tracheal lobe. In these cases bronchoscopy will show the normal position and trifurcation of the right upper lobe bronchus, allowing differentiation from the ectopic origin of a normal bronchus. For an accessory bronchus to be definitely designated as supernumerary it must be shown to supply lung parenchyma in excess of that normally encountered in the right upper lobe which has previously required bronchography. Tracheal lobes may lie in an extravlobar or intralobar position and usually have a vascular supply from the pulmonary artery. It is uncertain whether lung parenchyma supplied by an abnormal bronchus is intrinsically more susceptible to disease, however, most patients with tracheal bronchi are asymptomatic and need no specific treatment. In some patients disease occurs in the lung supplied by a displaced or supernumerary bronchus, usually in the form of bronchiectasis. Surgical excision of the involved segment has been necessary in such patients.

Our patient showed a true supernumerary tracheal bronchus that was distinguished from an ectopic bronchus by the normal anatomy of the right upper lobe bronchus. This case shows the ability of axial imaging to fully demonstrate a rare congenital abnormality of the bronchial tree. Computed tomographic scanning demonstrated the caudal course of the supernumerary bronchus and suggested the presence of the tracheal lobe, but was unable to define clearly the associated segment of lung. Magnetic resonance imaging showed the size and position of the tracheal lobe which, in this case, obviated the need for bronchography.

Replacement of one lung by a large bulla in active tuberculosis

Sulaiman A Al-Majed

A 70-year-old diabetic man with pulmonary tuberculosis developed a progressively enlarging bulla which occupied the whole left hemithorax and caused some shift of the mediastinum.

(Thorax 1995;50:427–428)

Keywords: tuberculosis, bulla, lung.

Large bullae are a known but rare complication of active tuberculosis. This is the first report of total replacement of one lung by a bulla which progressed in spite of successful chemotherapy.

Case report

A 70-year-old Saudi man was admitted to King Khalid University Hospital, Riyadh, with coughing, yellow sputum, fever, and sweating for one month. Diabetes had been diagnosed four months previously and he was treated with diet and an oral hypoglycaemic agent. He had never smoked and had no relevant occupational exposure. His chest symptoms persisted in spite of two courses of antibiotics. Chest radiography showed an infiltrate in the left mid zone without cavitation or elevation of the diaphragm. Bronchoscopic examination showed an inflamed, patent left main bronchus with multiple areas of ulceration. Abundant acid fast bacilli were seen in the bronchoalveolar lavage fluid. He was started on 300 mg isoniazid, 600 mg rifampicin, and 1.5 g pyrazinamide daily.

Figure 1 Chest radiograph showing two bullae in the left hemithorax.
A computed tomographic (CT) scan showed the left lung to be totally replaced by the bulla. Mediastinal windows showed no mediastinal lymphadenopathy. He was followed up for two years with no change on the chest radiograph or in spirometric values. The paralysis of the left recurrent laryngeal nerve persisted and the patient remained breathless on moderate exertion.

Discussion

Small cystic lesions of rapid onset (pneumatoceles) are a rare but well documented complication of tuberculosis. However, only 26 previous reports of bullae complicating tuberculosis were found, and in those reports the bullae regressed partially or completely on control of the infection.

The formation of bullae was first recorded after the advent of chemotherapy for tuberculosis 45 years ago, and previous workers have attributed this to the "lytic" effect of isoniazid.

Diabetes, which can exacerbate lung cavitation in tuberculosis, might have contributed to the two unique features of our case: the large size and the lack of regression of the bulla. We do not believe the paralysis of the recurrent laryngeal nerve was related to the presence of the bulla, but was probably the result of mediastinal tuberculous lymphadenopathy which had resolved by the time the CT scan was performed and is a documented cause for this paralysis.
