Decline of FEV₁ by age and smoking status: facts, figures, and fallacies

Huib A M Kerstjens, Bert Rijcken, Jan P Schouten, Dirkje S Postma

Assessment of pulmonary function testing plays a central role in everyday practice of the pulmonary physician. New patients are diagnosed and graded in severity on the basis of results from these tests, and the course of the disease in previously diagnosed patients is judged with the help of lung function measurements. The use of pulmonary function tests for these purposes requires a concept of what constitutes both a normal level and a normal decline and, consequently, an unusually low level and accelerated decline. The concept of a normal level is perceived to be fairly straightforward and is routinely deduced from some set of reference values. The population selection of the reference equations is taken to be sufficiently representative of the patient under study. In this review the problems associated with this assumption will be discussed and the cut off values between normal and abnormal examined. The same reference equations are often employed for the judgement of normal decline, assuming that the coefficient for age adequately represents decline in individuals. This approach, however, can be rather inadequate and this will be reviewed. Additionally, special reference will be given to estimating decline in smokers. Because of its ease of measurement and its very good reproducibility, the forced expiratory volume in one second (FEV₁) is the most widely used and quoted lung function test in clinical practice as well as in patient based research and in epidemiological studies of healthy subjects, and therefore the items discussed will be mainly centred around the FEV₁.

General course of FEV₁, over time

There is still considerable debate over the shape of lung function increase and decline during life. During childhood and adolescence there is naturally a rise in lung function, the exact shape of which is beyond the scope of this paper. For the period early in adult life, different shapes have been suggested. Although some authors have taken the decline in lung function to start at 15–20 years of age, others have found that the FEV₁ continues to rise to the age of 25 years, or even into the fourth decade. It is probably fair to say that in healthy individuals there is a plateau phase in early adulthood in which there is little or no change in FEV₁. The European Community for Coal and Steel stipulates that no change, assuming that the coefficient for age occurs between the ages of 18 to 25 and an accelerated decline in lung function compared with healthy individuals (line a). In real life more than one mechanism for a low level of FEV₁ in adult life can be operating in any one individual. Figure reproduced with permission from Weiss and Ware. As a result of these models of change in FEV₁, at any given time in adulthood FEV₁ is determined by three factors: (1) the maximally attained level of lung function during early adulthood; (2) the onset of decline of lung function or, alternatively, the duration of the plateau phase; and (3) the rate of decline of lung function (fig 1). In other words, from one low measurement of FEV₁ in an adult it is impossible to determine whether the reduced lung function is due to not having achieved a high maximum during early adulthood, to having had a shortened plateau phase, to having an accelerated rate of decline, or to any combination of these.

Cohort and period effects: discrepancies between estimates of decline derived from cross sectional and longitudinal studies

When following individuals over time, most clinicians assume FEV₁ to decline by the age
coefficient in the reference equations that are employed in their lung function laboratory. For instance, when using the ECCS equation, the average yearly decline from 25 years of age is assumed to be 29 ml/year for men and 25 ml/year for women. This essentially assumes that a 40 year old person will decline with the same ml/year as a 40 year old did 10 or 20 years ago when the equations were assembled. Moreover, it assumes that the equations were constructed in a longitudinal fashion—that is, actually looking at decline over time—whereas most equations used are derived from cross sectional analyses. Several studies have now shown that remarkable discrepancies exist between estimates of annual decline derived from cross sectional data sets as opposed to longitudinal data sets. In the two larger data sets the decline in FEV assessed longitudinally within individuals up to about 50 years of age has been found to be smaller than predicted from cross sectional analyses, whilst after that age the reverse is the case. In the Dutch Vlaardingen-Vlagtwedde study cross sectional age coefficients derived from the first survey overestimated the decline observed over 12 years of follow up in 20 year old individuals by 35 ml/year. By contrast, at the age of 60 the same procedure underestimated the decline by 11 ml/year for women. This essentially assumes that a 40 year old person will decline with the same year (Fig 2A). Similarly, in the Six Cities study the actual decline was underestimated by cross sectional estimates by 19 ml/year at the age of 75 (Fig 2B). The latter finding would be compatible with a survivor effect in cross sectional studies—that is, a selection of those having better lung function who still contribute to the data at an older age. This would cause cross sectional analyses to overestimate lung function at an older age and hence under-estimate the decline. Such a survivor effect was indeed demonstrable, but Ware and colleagues show that in their study it explained only a small part of the discrepancies at older age.

Apart from the mathematical and methodological problems in the actual production of reference equations as mentioned above, ad-

Reference values for healthy never-smokers

Problems associated with the use of reference values have been dealt with by several authors.9,10,12 For meaningful use of reference values to interpret a manoeuvre of FEV1 in a lung function laboratory, three important conditions have to be met: (1) the measurement of FEV1 derived in the laboratory should be reliable and its sources of variation should be known and appreciated;20 (2) the measurement techniques and conditions in the local laboratory should be comparable with those used in the study giving rise to the reference values; and (3) the population from which the reference values are derived should have characteristics encompassing those of the subject under study. Only when all three conditions have been met can a meaningful value for FEV1 % predicted be found and interpreted. A list of factors involved is given in table 1.

Both the European Respiratory Society and the American Thoracic Society have produced detailed recommendations on the procedures and techniques of lung function measurements which have recently been updated.9,20,27 In addition, the European guidelines provide reference equations which are a composite of earlier studies.9 By contrast, the American Thoracic Society has left the choice of reference values to the clinician, stating that although biological plausibility and simplicity in the model used to develop prediction equations are important issues, neither is as important as appropriate group selection and comparable instrumentation and technique.27 It is important to realise that some reference values currently in use have been put together before these recommendations were published and hence need not be the same as those currently in use in any given laboratory. This is especially true for the reference values for FEV1 of the European Community for Coal and Steel which are derived from 20 unrelated studies performed between 1960 and 1980 with varying apparatus, measurement conditions, and techniques.9

Five commonly used and two new reference equations are listed in table 2. Newer equations tend to be derived by increasingly elaborate statistical techniques such as polynomial equations5,10,12 and splines.8,28 As a result the clinician is left with either more complex equations for which software is sometimes available5,10,12 or even with no equations at all as, for instance, in the case of spline and smoothing techniques.8 In the latter case predicted value data can be used only within the same study.
The differences between prediction equations might at first sight seem to be of little relevance. However, to demonstrate that this is by no means always the case we calculated from different reference equations for a measured FEV₁ the corresponding % predicted FEV₁. For a 60 year old short man the measured FEV₁ can correspond to 65–102% predicted depending on the regression equation used (table 3). Thus, the choice of reference equations that are most suitable for the individual under study is of utmost importance. With life expectancy increasing, it is also important to realise that the current equations are less suitable for those aged above 75 years and new sets for the elderly have recently been proposed. Reference equations for non-Caucasian subjects – for example, Afro-Americans – are different from those for Caucasian subjects. A discussion of these non-Caucasian equations is beyond the scope of this paper.

* Extrapolation from the height range sampled.

The influence of environmental tobacco smoke begins in utero and has been convincingly documented in infancy. Active smoking has its effect on lung function within a few years of taking up the habit in adolescents, affecting both level and rate of growth. As a consequence, due to smoking during adolescence a lower maximum level and decline of lung function in their land-mark study of London workers. Several authors have shown that smoking shortens the plateau phase of FEV₁. The third factor determining the FEV₁ at any given time point – the rate of decline after the plateau phase – is the factor that has traditionally received the most attention. Fletcher and colleagues estimated the FEV₁ to be, on average, 390 ml lower for boys who smoke and 360 ml for girls.

Many more cross sectional studies in smokers than there are longitudinal studies. It should again be stated that the cross sectional studies by design will not be able to separate reliably the effects of smoking on the maximal level of FEV\textsubscript{1}, achieved in early adulthood, on the duration of the plateau phase, or on the rate of decline.\textsuperscript{19} Important observations have been reported in studies which document a dose-response relation in the effect of smoking on the rate of decline in pulmonary function, the effect being higher with more cigarettes, more years, or more pack years smoked.\textsuperscript{18,43-46} There are, however, substantial areas of uncertainty as to why only a minority of smokers are susceptible, and whether or not there are safe thresholds for smoking in those subjects. It is prudent to think there is not. The early identification of the susceptible smoker could lead to more targeted smoking prevention or smoking cessation programmes.\textsuperscript{47-49} Smoking cessation has been shown in many studies to result in normalisation of the decline in FEV\textsubscript{1}, to the rate of never smokers\textsuperscript{42, 44, 46, 50, 51} and this has recently been confirmed in a large scale intervention study.\textsuperscript{52} There seems to be a small positive effect on the level of FEV\textsubscript{1} separate from its effect on declining pulmonary function.\textsuperscript{53} Pipe and cigar smoking has also been found to accelerate the decline in FEV\textsubscript{1}.\textsuperscript{44, 53} There is, to date, little clarity on sex differences in the susceptibility to cigarette smoke, with similar numbers of studies reporting that men are more susceptible\textsuperscript{42, 51, 53-55} and that women are more vulnerable.\textsuperscript{18, 37, 44, 54-57} It has been shown by several authors that symptomatic smokers have larger declines than non-symptomatic smokers.\textsuperscript{58, 59} Although weight per se does not enter as a significant factor into any of the regression equations for FEV\textsubscript{1} given in the table, a negative effect of weight gain on decline in pulmonary function has recently been reported in two studies.\textsuperscript{59, 60} The loss of FEV\textsubscript{1} due to increase in weight associated with smoking cessation therefore counteracts to some degree the positive effect of smoking cessation itself on FEV\textsubscript{1}.

Other risk factors associated with accelerated decline of FEV\textsubscript{1}

When interpreting the results of (changes in) FEV\textsubscript{1}, it is important to realise that smoking is not the only known risk factor for accelerated decline in lung function, though it is by far the most important one both in epidemiological settings and in patients with already manifest disease. Some patients with asthma show accelerated decline in FEV\textsubscript{1}.\textsuperscript{51-55} Since chronic obstructive pulmonary disease (COPD) is usually associated with smoking, and smoking is the primary risk factor for accelerated decline, it is unclear whether the disease by itself gives rise to accelerated decline. In patients with COPD and mild to moderate obstruction, cessation of smoking seems to move the decline in pulmonary function back into the normal range.\textsuperscript{32} Risk factors for accelerated decline among subjects with already clinically manifest obstructive disease have also recently been reviewed,\textsuperscript{61} next to smoking, increased airway hyperresponsiveness was the only factor consistently found to predict a more rapid decline.\textsuperscript{59, 60} Studies of general population samples (as opposed to patients with already manifest disease) have identified the following risk factors for accelerated decline which are reviewed elsewhere: airways hyperresponsiveness,\textsuperscript{69, 70} atopy,\textsuperscript{69} childhood respiratory infections,\textsuperscript{71} air pollution,\textsuperscript{72} and occupational hazards.\textsuperscript{73, 74}

Is this lung function abnormal?

Measurement of lung function is subject to large variation and age, height, and sex in prediction equations only account for some
Decline of FEV1 by age and smoking status

40–50% of any forced vital capacity measured.20 Such data are not available for FEV1 but should be comparable. It is less appreciated that the interpretation of the results of a given test result by pulmonary physicians is also subject to considerable variation; when 26 pulmonary physicians were asked to grade obstruction in 10 consecutive patients as none, mild, moderate, or severe, only 60% agreement was obtained.21 Part of this confusion stems from a lack of common concept of normality.20 22–47.77 Three methods are available to determine the lower limit of normal FEV1: (1) a fixed percentage below the predicted value; (2) a fixed point of the normal Gaussian distribution, most commonly the 5th percentile; and (3) the actual percentile curves. Unfortunately, the first method of assessing “abnormality” is still by far the most commonly used method by clinicians and 80% predicted is the commonly used limit. This method has no logical background and has, in fact, been proven to be inappropriate by many authors over the last four decades.23 9 12–25.78–81 Why does the method persist? Probably for two reasons—primarily because it is the easiest method to use, and also because it has been used for such a long period both by clinicians and researchers. The reason why the fixed percentage criterion should be abandoned is that the boundary between acceptable and unusually low function in large population studies is not proportional to the mean value, but instead the distribution is homoscedastic—the loss, for instance, of 0.84 litres is just as unusual for an old as for a young man, and for a tall as for a short man. In other words, 5% of the healthy young tall population have values as low or lower than this volume below predicted, and similarly 5% of the short old population (fig 3).78 The second and third methods of assessing normality have a common statistical basis. The third method, which uses percentile curves, is the best method from a statistical perspective,76 80 and although not in vogue in pulmonary medicine, it has been used to great advantage for many years in paediatrics for growth curves (height for age, weight for height, etc). In cases where the distribution of values around the predicted value is Gaussian across all ages and heights, the 95% percentile should be the same as 1.64 times the standard deviation of the residuals (sometimes called the residual standard deviation, RSD). This is the abovementioned second method. In the case of the European Community for Coal and Steel equations, the distribution in fact turns out to be sufficiently Gaussian to justify the use of 1.64 RSD or the 5th centile as the cut off value, representing values of 0.84 l as the cut off for men and 0.62 l for women.9 This method is easier to implement in clinical practice than the use of percentile curves for different heights and sexes. The underlying assumption is that it is deemed acceptable that 5% of the normal population be classified as having an abnormally low lung function. Results of function tests should then be expressed in the number of RSDs below predicted instead of in % predicted. Only a few lung function laboratories appear so far to have taken up this statistically more logical approach, and many clinicians remain reluctant. Likewise, selection of patients for having an abnormal lung function in a research setting should preferably also be performed utilising RSD.82 Fortunately, software of newer lung function devices increasingly renders the FEV1 is homoscedastic—the loss, for instance, of 0.84 litres is just as unusual for an old as for a young man, and for a tall as for a short man. In other words, 5% of the healthy young tall population have values as low or lower than this volume below predicted, and similarly 5% of the short old population (fig 3).78 The second and third methods of assessing normality have a common statistical basis. The third method, which uses percentile curves, is the best method from a statistical perspective,76 80 and although not in vogue in pulmonary medicine, it has been used to great advantage for many years in paediatrics for growth curves (height for age, weight for height, etc). In cases where the distribution of values around the predicted value is Gaussian across all ages and heights, the 95% percentile should be the same as 1.64 times the standard deviation of the residuals (sometimes called the residual standard deviation, RSD). This is the abovementioned second method. In the case of the European Community for Coal and Steel equations, the distribution in fact turns out to be sufficiently Gaussian to justify the use of 1.64 RSD or the 5th centile as the cut off value, representing values of 0.84 l as the cut off for men and 0.62 l for women.9 This method is easier to implement in clinical practice than the use of percentile curves for different heights and sexes. The underlying assumption is that it is deemed acceptable that 5% of the normal population be classified as having an abnormally low lung function. Results of function tests should then be expressed in the number of RSDs below predicted instead of in % predicted. Only a few lung function laboratories appear so far to have taken up this statistically more logical approach, and many clinicians remain reluctant. Likewise, selection of patients for having an abnormal lung function in a research setting should preferably also be performed utilising RSD.82 Fortunately, software of newer lung function devices increasingly renders the FEV1 is homoscedastic—the loss, for instance, of 0.84 litres is just as unusual for an old as for a young man, and for a tall as for a short man. In other words, 5% of the healthy young tall population have values as low or lower than this volume below predicted, and similarly 5% of the short old population (fig 3).78

Figure 3 Set of hypothetical points relating some parameter to a physiological function. Solid line in middle of dots represents regression line for these points. Broken line represents limits of normal (A) 20% below the regression line and (B) 2 SE of the estimate below the regression line. Since the variance—that is, the scatter of points around the regression line—is uniform regardless of the point on the regression line one chooses, the degree of deviation from regression is fixed and the use of percentage as in (A) is invalid. FEV1 and VC data have this characteristic of uniform variance so that the use of 2 SE is legitimate. Reproduced with permission from Sobol.78
function should be derived as 5th percentiles employing the standard error of the estimate from regression equations of decline exactly as explained above using RSD for level of FEV\textsubscript{1}. These regression equations involve quadratic terms of age.\textsuperscript{11,15}

Conclusions

Interpretation of a given FEV\textsubscript{1}, the light of what is an unusually low value and what is well within the common range is daily practice for the clinician. Although a clinical judgement should never be based solely on the results of a lung function test, the judgement of the physician can have large personal, social, legal, and economic consequences. However, the interpretation is not always as straightforward as it may seem at first glance.

For the proper interpretation of any measured FEV\textsubscript{1}, the sources of variation in one’s own laboratory should first be appreciated. There is considerable variation due to technical and patient related sources. It is also essential that the reference equations chosen should be appropriate for the subject under investigation.

It has long been shown that smoking – both active and passive – has a negative influence on lung function, particularly cigarette smoke which influences all three determinants of an FEV\textsubscript{1} at any given time during adult life – the peak achieved during early adulthood, the duration of the ensuing early adulthood plateau phase, and the rate of subsequent decline. On average, moderate to heavy male smokers roughly have a 15 ml/year larger decline in lung function than non-smokers.

Finally, most reference values currently in use are of a cross sectional nature and are therefore not well suited for predicting decline within individuals.

HK is the recipient of a grant from the Niels Nielsen Foundation and is currently at the Asthma Research Group, Hamilton, Ontario.
