Abstract

Background—Serum angiotensin converting enzyme (SACE) is considered to reflect disease activity in sarcoidosis. SACE activity is increased in many patients with active sarcoid lesions. The mechanism for the increased SACE activity in this disease has not been clarified. ACE insertion/deletion (I/D) gene polymorphism has been reported to have an association with SACE levels in sarcoidosis, but no evidence of an association between angiotensin II receptor gene polymorphism and SACE in this disease has been found. A study of the association of angiotensin II receptor gene polymorphisms with sarcoidosis was therefore undertaken.

Methods—ACE (I/D), angiotensin II type 1 receptor (AGTR1), and angiotensin II type 2 receptor (AGTR2) gene polymorphisms were investigated by polymerase chain reaction (PCR) and SACE levels were measured in three groups of patients: those with sarcoidosis or tuberculosis and normal controls.

Results—There was no difference in allele frequency of AGTR1 and AGTR2 polymorphism among the three groups. Neither AGTR1 nor AGTR2 polymorphisms were associated with sarcoidosis. SACE activity was higher in patients with sarcoidosis than in others. However, this tendency was not detected in patients with tuberculosis.

Conclusions—The AGTR1 allele C is associated with high activity of SACE in patients with sarcoidosis. It is another predisposing factor for high levels of SACE activity in sarcoidosis. This fact could be one of the explanations for the increased SACE activity in sarcoidosis.

Keywords: angiotensin II receptor gene; polymorphism; angiotensin converting enzyme

Sarcoidosis is a chronic multisystem disorder of unknown aetiology characterised in affected organs by accumulation of T lymphocytes, mononuclear phagocytes, and non-caseating epithelioid granulomas. High serum angiotensin converting enzyme (SACE) activity has been reported specifically in patients with sarcoidosis and is considered to reflect disease activity. High SACE activity in patients with sarcoidosis is associated with a poorer prognosis than those with lower activity. However, the precise mechanism of increased SACE activity in this disease has not yet been clarified.

Genetic polymorphism studies in many diseases have recently revealed new aspects of clinical importance. ACE I/D (insertion and deletion) polymorphism has also been studied and the ACE D allele is reported to be a predisposing factor for high SACE levels in patients with sarcoidosis. ACE is an enzyme which converts angiotensin I to angiotensin II and the new formed angiotensin II then acts on angiotensin receptors. Two types of angiotensin receptors have been cloned in humans (type 1 (AGTR1) and type 2 (AGTR2)), and their polymorphism and sequences have been identified. AGTR1 A/C polymorphism represents the transition of A to C, which is an untranslated region and may be non-functional. The clinical significance of this polymorphism has not so far been studied but it might have some relation to SACE levels in this disease. In this study we have investigated whether some displacement of these receptor polymorphisms occurs specifically in patients with sarcoidosis.

Methods

SUBJECTS

One hundred patients with sarcoidosis, 50 patients with pulmonary tuberculosis, and 247 normal control subjects were studied. All patients were Japanese and the mean (SD) ages of those with sarcoidosis and tuberculosis were 49.4 (12.7) and 51.6 (15.2), respectively. Patients were followed up in National Kinki Central Hospital and Osaka Prefectural Hospital from July 1996 to July 1997. Two hundred and forty seven normal subjects were analysed at the Department of Geriatric Medicine, Osaka University, 96 of whom were used as controls in the study of an association between SACE levels and genetic polymorphisms. The diagnosis of sarcoidosis was based on clinical findings and histological findings of non-caseating granulomas, and a diagnosis of pulmonary tuberculosis was based on the

Results

The frequency of ACE polymorphism in patients with sarcoidosis was not significantly different from that in control subjects and those with tuberculosis (table 1), nor was there a significant difference in the frequency of AGTR1 polymorphism between the three groups (table 1). A difference in allele frequency appeared in AGTR2 polymorphism between patients with tuberculosis and control subjects ($\chi^2 = 45.02$, p<0.001) but no...
SACE activity in patients with sarcoidosis

461

The ACE D allele is reported to be a predisposing factor to high SACE levels both in normal subjects and in patients with sarcoidosis. In our study of Japanese patients with sarcoidosis, tuberculosis, and normal controls the ACE D allele was also associated with higher SACE levels than the ACE I allele. SACE levels differ among races which may be due to the heterogeneity of ACE I/D polymorphism. Black patients with sarcoidosis have higher SACE activity than white subjects and Japanese. Such an association has not explained the mechanism of high SACE activity in patients with sarcoidosis, but ACE I/D polymorphism may be one of the genetic factors responsible for this. From a study of familial clustering, high prevalence and clinical severity of sarcoidosis in African Americans Rybiki et al concluded that the heterogeneity of the risk of familial sarcoidosis might have several aetiologies.

The importance of AGTR1 polymorphism has been reported in addition to ACE polymorphism in cardiovascular disease, hypertension, and arteriosclerosis. Here we have noted a significant increase in SACE activity in patients with AGTR1 AC genotype (p<0.05) compared with AA genotype and CC genotype (table 1).

The frequency of AGTR1 CC genotype (2%) was too infrequent for statistical analysis, as Tietre has reported previously. AGTR1 A/C116 polymorphism in patients with sarcoidosis shows high SACE activity, in contrast to patients with tuberculosis and normal controls. We conclude that the presence of the AGTR1 A allele in sarcoïdosis has a specific association with SACE levels in patients with sarcoidosis (p<0.05). Changes of amino acid at polymorphic sites in ATGRI are not associated with cardiovascular disease and no mutation in the coding region of AGTR1 was identified in a group of 50 hypertensive patients. SACE activity does not appear to predispose to hypertension in patients with sarcoidosis. This suggests that the angiotensin II signal may not be conveyed, so the association of the AGTR1 A allele with sarcoidosis may involve functional mutations in the coding sequences of AGTR1.

Tietre et al reported that the AGTR1 C allele substantially increases the effect of ACE D allele on the risk of myocardial infarction in a low risk group. Bonnardeaus et al found that the ACE I allele is weakly associated with aortic elasticity in hypertension and the AGTR1 C allele is a strong determinant of this. The ACE D allele shows less SACE activity than the ACE I allele in subjects with sarcoidosis who have the AGTR1 C allele and the opposite is true in a subgroup with the AGTR1 A allele. Both ACE and AGTR1 polymorphisms which favour an increase in SACE activity in patients with sarcoidosis may have an inverse effect rather than a synergistic effect. One of the mechanisms of AGTR2 polymorphism does not disclose any association in patients with sarcoidosis. In patients with tuberculosis the significant difference in allele frequency in AGTR2 is dependent on sex because AGTR2 is located on the X chromosome. The functions of AGTR1 are threefold: breakdown of phosphoinositide by stimulation of phospholipase C resulting in the release of intracellular Ca++, activation of voltage dependent Ca++ channels, and inhibition of adenylate cyclase activity. The function of AGTR2 is known to be different from AGTR1 but it has not been clearly identified. AGTR2 polymorphism does not affect SACE activity in patients with sarcoidosis.
In conclusion, the results of our study support the findings that AGTR1 polymorphism manifests an additional predisposition to high SACE activity in patients with sarcoidosis. The AGTR1 C allele is associated with SACE in patients with sarcoidosis and affects SACE levels independently of the ACE D allele. Further studies are warranted to clarify the possibility of a link between mutations on AGTR1 and high SACE activity in patients with sarcoidosis.
