Letters to the Editor

Multidrug resistant tuberculosis

We read with interest the report by White and Moore-Gillon on the resource implications of multidrug resistant tuberculosis (MDR-TB) in the UK. We studied the outcome of 44 HIV negative patients with MDR-TB admitted to two tertiary care tuberculosis units in the Netherlands between 1985 and 1998. Most (38 patients) had pulmonary tuberculosis. The mean admission period was 164 days and all patients received an individually tailored combination of antituberculous drugs for a mean period of 608 days. We estimated the cost of treatment per patient to be US$60 000 which included admission fee, costs for outpatient visits, and the costs of drug provision. Although we did not include cost of toxicity monitoring and additional procedures, our costs compare favourably with those of White et al. (mean £60 000) and Mahmoudi (mean US$180 000).

In the Netherlands the number of patients with tuberculosis resistant to any antituberculous drugs is limited to 11%, and only 0.6% of the bacilli are MDR. Between 1993 and 1997 only 43 cases of MDR-TB were identified, of which 28% had received previous treatment for tuberculosis (Index Tuberculosis 1998, Royal Netherlands Tuberculosis Association, The Hague, 2000). This suggests that transmission of MDR bacilli rather than inadequate treatment contributes to the resistance problem in the Netherlands.

In poor resource countries, directly observed short course chemotherapy of tuberculosis is generally recommended to prevent the occurrence of MDR-TB. We feel that new rapid molecular methods for detecting resistance should be developed to limit the period of potential (nosocomial and community) transmission of MDR bacilli and thus prevent the emergence of MDR-TB. Such tests should then be made available to poor resource countries at an affordable price.

Cost of physiotherapy in CF

Increasing survival is associated with increasing numbers of adults with cystic fibrosis (CF). It is recognised that management at specialist CF units is associated with improved health outcomes. Assessment of the staff allocation and resources to adults with CF and accurate costing of these services are essential to evaluate the cost effectiveness of the existing CF services and prediction of future requirements. Global costs of care for young people with CF have been estimated, but studies of the cost of providing physiotherapy for a CF service are scarce.

The utilisation and cost of providing a physiotherapy service for patients with CF was determined from February to June 1999 (late summer, autumn and early winter). Using staff designation (pay level), time of physiotherapy (in 5 minute unit allotments), and after hours received, comparison was made with actual funding for the service. At the time of the study the Adult CF Unit at the Prince Charles Hospital in Brisbane provided clinical care for 120 adults with CF from throughout Queensland, with patients travelling up to 1800 km. Despite an active home intravenous antibiotic programme, many patients require admission for treatment of pulmonary exacerbations. Physiotherapy management included respiratory therapy, education, and exercise and was available to all inpatients with CF on a 24 hour basis when required. Outpatient and domiciliary physiotherapy service provision were excluded from this study.

During the 5 month study period (150 days) there were 102 inpatient admissions in 58 patients (mean length of stay 21.1 days). Two patients (with two admissions each) were inpatients for a total of 116 and 129 days, respectively, and two patients died during the study. In 5 months 1498 hours of physiotherapy were provided at a cost of £1 370.00 (AUD3370.00) per patient per day. This involved a mean of 9.9 hours of physiotherapy per day. This cost exceeded funding for the service by 28% (£630/month). The total time of physiotherapy varied from 233 to 401 hours per month. The majority of the service was provided during normal working hours (72.9%). Due to penalty wage rates for after hour’s work, only 58.5% of the total cost was provided during normal working hours. The weekend and public holiday physiotherapy used 22.8% and 3.3% of the time but accounted for 33.6% and 6.8% of cost, respectively. Physiotherapy care provided during weekday evenings amounted to 1% of total time and total cost.

This analysis shows that the cost of inpatient physiotherapy in a tertiary referral service is £12.18 (A$25.34) per day or £12 per patient per day. Provision of a service outside normal working hours accounts for a significant proportion of the cost of this service. Regular analysis of time utilisation is required to determine if adequate staffing levels and funding are available to meet the challenge of an increasing population of adults with CF.

Systemic effects of inhaled steroids

The recent article by Harrison and colleagues has limitations which were not adequately addressed. It was perhaps hardly surprising to find no differences in plasma budesonide concentrations between normal and asthmatic subjects due to the relatively insensitive assay compared with fluticasone. The respective dry powder inhaler devices for each drug differ markedly in their fine particle dose delivery and therefore in clinical efficacy. Using the Accuhaler, the peripheral lung deposition and, in turn, systemic absorption. The fine particle dose expressed as a percentage of the nominal dose for fluticasone Accuhaler (Diskus) is 12% compared with 40% for budesonide Turbuhaler. Moreover, there is a much higher proportion of coarse particles from the Accuhaler than from the Turbuhaler. The study was therefore biased towards showing greater attenuation of peripheral lung absorption with fluticasone Accuhaler in asthmatic subjects.

The authors state that they are unaware of any previous direct comparisons of the effects of fluticasone and budesonide on osteocalcin concentrations. In adult asthmatic subjects steady state dosing for 12 days showed greater percentage suppression with fluticasone than with budesonide of 0.80 hour plasma cortisol levels compared with placebo (48% v 20%) which was mirrored by suppression of 0.80 hour serum osteocalcin levels (37% v 12%). This was therefore biased towards showing greater attenuation of peripheral lung absorption with fluticasone Accuhaler in asthmatic subjects.

Pulmonary infiltrates in non-HIV patients

We read with interest the article by Rano et al in the May edition of Thorax.1 This group showed that, by using non-invasive methods (blood cultures, sputum cultures, nasopharyngeal washes and tracheobronchial aspirates), they were able to make a positive diagnosis in 41% of 200 non-HIV immunocompromised patients with pulmonary infiltrates.

We have looked at a similar group of patients treated in the Leukaemia and Lymphoma Units at the Royal Marsden Hospital who needed investigation for pulmonary infiltrates and found a low diagnostic yield from bronchoscopy with neither a positive result (36%) nor a change in management (28%) making any impact on survival. Like Rano et al, we are therefore keen to use the evaluation for non-invasive investigations.

From our literature review we found many groups advocating the use of high resolution CT scanning (HRCT) of the chest. It has found particular usefulness in those patients with a normal chest radiograph but respiratory symptoms and fever, having a negative predictive value after bone marrow transplantation of 97%. The HRCT scan has characteristic appearances in aspergillosis,2 Pneumocystis carinii pneumonia (PCP),3 and cytomegalovirus (CMV) infection.4 One group has compared HRCT and bronchoalveolar lavage (BAL) in the diagnosis of fungal pneumonia and found the former to be superior.5 From these data it seems that such characteristic appearances on CT scanning could obviate the need for bronchoscopy.6

The paper by Rano et al isolates 15% were of A fumigatus and four (2%) were of PCP. Do the authors feel that these patients might have been diagnosed by HRCT scanning and thus have avoided bronchoscopy altogether?

Antifungal treatment was only instigated after 4–5 days if there was no improvement or positive microbiology. With such a policy the mortality rate in those with Aspergillus infections was 67%. Other groups recommend early introduction of antifungal treatment due to its high prevalence, particularly in haematological malignancies.7 In the light of their results and the potential of early HRCT scanning, have the group changed their practice to include early use of antifungal treatment?

A TATTERSFIELD

 AUTHORS’ REPLY We appreciate the valuable comments by Drs Murray and O’Brien regarding our study on immunocompromised patients. In our study the diagnostic yield of non-invasive methods was 41%. The good results obtained with these techniques, as well as their availability and relatively low cost, make them very useful in the clinical management of immunocompromised patients. In this sense, HRCT scanning, as Drs Murray and O’Brien point out, has a demonstrated role in the diagnosis of some pulmonary complications, particularly Aspergillus pneumonia, and can be included in the diagnostic strategies of non-invasive diagnostic techniques. Whether or not an HRCT scan might facilitate the early start of antifungal treatment and improve the mortality from Aspergillus pneumonia will need to be evaluated in properly designed studies.

Although non-invasive techniques must be considered as a first step in the clinical management of immunocompromised patients, their use cannot justify any delay in performing a bronchoscopic exploration. In this study, contrary to the experience reported by Drs Murray and O’Brien, the systematic use of endoscopic techniques allowed us to increase the diagnostic yield up to 81%. We believe that obtaining an early diagnosis in immunocompromised patients is of paramount importance. In fact, the low diagnostic yield of the 25 bronchoscopies performed in the series by Murray et al and the lack of impact on survival, also reported by other groups, may well be due to the fact that the endoscopic techniques are performed too late in the evolution of the disease when the possibilities of influencing the outcome are very few.

Replacing bronchoscopic techniques by HRCT scanning carries the risk of misdiagnosing polymicrobial lung infectious and non-infectious pulmonary complications in which bronchoalveolar lavage and bronchial aspirates have a known diagnostic role. Remarkably, in 11 of the 15 polymicrobial infections reported in our series, both Aspergillus and/or cytomegalovirus (CMV) were involved. In these cases the use of HRCT scanning instead of bronchoscopy would probably have missed one of the other co-existent pathogens. We therefore do not believe that HRCT scanning of the chest can replace bronchoscopy in the clinical management of immunocompromised patients with pulmonary infiltrates.

Severe bullous emphysema associated with cocaine smoking

Pulmonary emphysema is characterised by permanent enlargement of airspaces distal to the terminal bronchiole accompanied by destruction of alveolar walls. The loss of elastic tissue contained in the interalveolar septa is caused by an imbalance between proteinases and antiproteinases, activity, most commonly caused by cigarette smoking. Congenital deficiency of α1-antitrypsin, the most well known antiproteinase, is an important risk factor for the development of premature emphysema. In addition, various other causes have been reported including intravenous drug abuse, particularly Ritalin. More recently, Johnson et al reported four cases of bullous emphysema associated with marijuana smoking. We want to report an additional case of severe premature bullous emphysema in a man with a longstanding history of cocaine smoking. To the best of our knowledge, this relationship has only once been reported in the Spanish medical literature.

A 40 year old man was admitted with progressive dyspnoea, cough, and fever. According to his relatives he had been smoking cocaine (so called “free basing”) for the past 17 years. A reliable history of tobacco smoking could not be obtained because of his respiratory distress and poor level of consciousness. His medical history consisted of recurrent respiratory tract infections. Chest
radiographs and computed tomographic scans showed impressive bilateral bullous emphysema with a large air-fluid collection in the right lung, suggesting pulmonary abscess formation (figs 1, 2, 3). Because of progressive respiratory failure he was intubated and mechanically ventilated. Further treatment consisted of intravenous broad spectrum antibiotics (clindamycin and ceftazidime followed by amoxicillin-clavulanic acid) and chest tube drainage because of ventilator associated pneumothorax. The patient eventually died of treatment resistant respiratory failure as a result of pneumonia in the scarred residual pulmonary tissue. Sputum cultures yielded Mycobacterium tuberculosis and Streptococcus species. HIV infection was excluded serologically. The definitive diagnosis of cocaine induced pulmonary emphysema was established after the concentration of α1-antitrypsin was found to be within the normal range.

Besides congenital α1-antitrypsin deficiency, cocaine smoking should be considered as a possible cause of severe premature bullous emphysema. Abscess formation and rapidly progressive respiratory failure may complicate this condition.

Side effects of antituberculous treatment

Combined antimycobacterial chemotherapy has been shown to be very effective in the treatment of Mycobacterium tuberculosis hominis (MTH) pulmonary infections with a cure rate of >85% for short term (6 month) courses.1 Recent WHO initiatives have been launched and are aimed at eradicating pulmonary tuberculosis by intensive adoption of directly observed treatment (DOT) strategies in countries in which the incidence is high.

A new drug formulation has recently been produced which provides the three main first line drugs in the same tablet in a fixed ratio (rifampin (RIF) 120 mg, isoniazid (INH) 50 mg, and pyrazinamide (PZM) 300 mg).2 This formulation is likely to be extremely useful, particularly in developing countries where it can provide reliable simultaneous administration of all the drugs needed on bi-weekly or tri-weekly DOT programmes.3 However, it is not intended to substitute any (or all) of the single components in countries where they are already available and marketed.

In a recent WHO report, of all the industrialised European countries, Italy reported the highest prevalence of multidrug resistance among previously treated cases of tuberculosis (33.9%, 95% CI 23.9% to 42.7%), with any drug resistance accounting for up to 60.6% of the strains.4 In addition, there was a high prevalence of resistance in new cases of tuberculosis with 12.3% resistance to any drug.5

In Italy the distribution and marketing of PZM ceased as a single drug formulation between 15 June 2000 and early 2001. This abrupt policy change temporarily introduced a new and interesting challenge to the treatment of MTH, and possibly increased risks of toxicity and decreased treatment efficiency for some patients.

Over the last 2 years we have treated 26 patients with pulmonary tuberculosis using the standard four drug regimens administered as single drugs and have recorded a relatively high rate of hepatotoxicity (35%) compared with other studies North American and European analyses (11%).6 7 In eight of the nine patients with hepatotoxicity the substitution of INH led to normalisation of liver function. This incidence of side effects approaches the incidence of side effects (26%) reported in a European study of similar design on 519 patients of similar mean age.

In our 26 patients we estimated that, if a fixed dose formulation had been used to maintain the dose of RIF at 10 mg/kg/day, a significantly increased dose of PZM (not correlated to the one that was actually given) would have been administered. Thus, it is reasonable to suggest that the already high rate of toxicity could increase in incidence and severity when PZM is administered daily as a fixed dose formulation. When considered in the context of the unavailability of PZM single drug formulations, two additional considerations are warranted.

Firstly, there is a limited choice of first line regimens which exclude INH for patients with INH related hepatotoxicity (for example, RIF+STM+EMB but not RIF+PZM+STM). Side effects in hospital treated patients usually lead to withdrawal of one of the basic drugs and replacement by other drugs such as ethambutol or streptomycin. This may lead to more prolonged treatment and to decreased adherence.8 However, these negative consequences would be considerably enhanced if single drug formulations of PZM are not available since withdrawal of at least two first line drugs would be needed (PZM + INH).

Secondly, the treatment of patients with chronic tuberculosis who are infected with the most frequent INH or RIF resistant MTH (43.3% and 44.9%, respectively)9 or with multidrug resistant MTH could lead to the drug being acquired from abroad at high cost, and sometimes to interruptions in the supply with dangerous consequences for the patient’s health. In fact, most tuberculosis units in our area acquired PZM as a single drug formulation from neighbouring countries during the time when it was not available.

Thus, available data do not support the use of fixed dose formulations as the only treatment choice in developed countries. This could be particularly dangerous where there is a high prevalence of multiple drug resistant MTH, including developing countries.
