Prospective study of the incidence, aetiology and outcome of adult lower respiratory tract illness in the community

J Macfarlane, W Holmes, P Gard, R Macfarlane, D Rose, V Weston, M Leinonen, P Saikku, S Myint

Abstract

Background—Acute lower respiratory tract illness in previously well adults is usually labelled as acute bronchitis and treated with antibiotics without establishing the aetiology. Viral infection is thought to be the cause in most cases. We have investigated the incidence, aetiology, and outcome of this condition.

Methods—Previously well adults from a stable suburban population consulting over one year with a lower respiratory tract illness were studied. For the first six months detailed investigations identified predetermined direct and indirect markers of infection. Evidence of infection was assessed in relation to presenting clinical features, indirect markers of infection, antibiotic use, and outcome.

Results—Consultations were very common, particularly in younger women (70/1000 per year in previously well women aged 16–39 years), mainly in the winter months; 638 patients consulted, of whom 316 were investigated. Pathogens were identified in 173 (55%) cases: bacteria in 31, Strepotoccus pneumoniae (54, 82), Chlamydia pneumoniae (7), atypical organisms in 75 (Chlamydia pneumoniae 55, Mycoplasma pneumoniae 23), and viruses in 61 (influenza 23). Seventy nine (24%) had indirect evidence of infection. Bacterial and atypical infection correlated with changes in the chest radiograph and high levels of C reactive protein but not with (a) the GP’s clinical assessment of whether infection was present, (b) clinical features other than focal chest signs, and (c) outcome, whether or not appropriate antibiotics were prescribed.

Conclusions—Over 50% of patients have direct and/or indirect evidence of infection, most commonly bacterial and atypical pathogens, but the outcome is unrelated to the identified pathogens. Many patients improve without antibiotics and investigations do not help in the management of these patients. GPs can reassure patients of the causes and usual outcome of this self-limiting condition.

Keywords: adult lower respiratory tract illness; acute bronchitis; pathogens; general practice

Episodes of acute respiratory illness are the most common reason for consulting a general practitioner (GP) in the UK. Many are called “acute bronchitis” and are labelled as infection, with little knowledge of the true aetiology, and are treated with antibiotics despite numerous studies demonstrating little overall benefit. No studies have investigated in detail the causes of community acquired lower respiratory tract illness (LRTI) or acute bronchitis, although viral infections are generally thought to be the most important cause. This makes it difficult to provide evidence based advice about management strategies for this common condition.

We describe a year long prospective study of the incidence, aetiology, and outcome of LRTI in a defined population of previously well adults.

Methods

Ten GPs from two practices serving a suburban population of 14 453 adults aged 16 and over recorded structured data on all previously well adults consulting with acute LRTI (defined in

Box 1  Definitions used.

- Previously well patients were defined as not under supervision or management for an underlying disease—for example, patients with asthma, chronic obstructive pulmonary disease, heart disease, and diabetes were not included.
- Lower respiratory tract illness (LRTI) required all of:
  (a) an acute illness present for 21 days or less;
  (b) cough as the cardinal symptom;
  (c) at least one other lower respiratory tract symptom (sputum production, dyspnoea, wheeze, chest discomfort/pain);
  (d) no alternative explanation—for example, not sinusitis, pharyngitis, or a new presentation of asthma.
A. Specimens obtained by the research nurse (number (%)) of that investigation collected from the 316 patients

- Two throat swabs for bacterial and viral studies (316, 100%).
- Blood for serology initially (315, 99%) and about 10 days and one month later (triple or paired serum samples in 300).
- Sputum (273, 86%), assisted by saline nebulisation when necessary.
- Chest radiograph at the City Hospital and reviewed “blind” by our radiologist (289, 92%; 232, 80% within 3 days; and 287, 99% within 5 days).

B. Definition of direct evidence of infection

- Isolation of a bacterial respiratory pathogen from diluted sputum.
- At least a fourfold rise in antibody titre to viral and atypical pathogens.
- Detection of Chlamydia pneumoniae IgM in serum.
- Detection of pathogens in throat swabs by culture (for influenza viruses A and B, parainfluenza, adenovirus and RSV) or gene amplification (for coronavirus, human rhinovirus, Mycoplasma pneumoniae and C pneumoniae).
- At least a threefold rise in antibody titres to Haemophilus influenzae and Moraxella catarrhalis.
- Pneumococcal infection required detection of one or more of sputum pneumococcal capsular antigen, serum pneumococcal immune complexes (ICs) including pneumolysin-specific IC (in a titre of ≥100), pneumococcal surface antigen IC (titre ≥100), C-polysaccharide-specific IC (titre ≥150), or a twofold or greater rise in pneumolysin and C-polysaccharide-specific antibodies.10

C. Definition of indirect evidence of infection included one or both of:

- The presence of chest radiographic changes consistent with infection.
- High C reactive protein (CRP) of 50 mg/l or more.

D. Patient groupings used in the analysis included:

- Group 1: evidence of bacterial and/or atypical infection (and who consequently might be expected to benefit from antibiotics).
- Group 2: evidence of viral infection only or no direct evidence of infection (in whom antibiotic treatment would theoretically be unhelpful).

Box 2 Specimens obtained, the definition of infection used, and infection groupings used for the analysis.
Indirect evidence of infection

Seventy-nine patients (24%) had indirect evidence of infection. Forty-eight chest radiographs (17%) showed changes consistent with infection; 17 (6%) fulfilled the British Thoracic Society definition of radiographic pneumonia. Fifty patients (16%) had a high CRP level (which we defined as 50 mg/l or over).

There was a significant relationship between chest radiographic changes and high CRP levels; of 48 patients with chest radiographic changes consistent with infection, 19 (40%) had a high CRP level compared with 26/241 (11%) who had no changes consistent with infection (p<0.0005). Of the 17 patients with radiographic pneumonia, 11 (65%) had a high CRP level.

Relationship between direct and indirect evidence of infection

The 137 patients in group 1 (bacterial/atypical pathogens identified) more commonly had indirect evidence of infection than the 179 patients in group 2 (viral/no pathogens identified). High CRP levels were found in 31/137 (23%) of group 1 compared with 19/179 (11%) who had no changes consistent with infection (p=0.0004). Chest radiographic changes consistent with infection occurred in 32/129 (25%) of patients in group 1 who underwent radiography and 16/160 (10%) of group 2 (p=0.0008).

When specific bacterial and atypical pathogen groups were analysed individually within group 1, only C pneumoniae was not associated with indirect evidence of infection.

Clinical features and clinical assessment

Clinical features were similar for the two groups (data not shown) except that patients in group 1 more often had focal signs on chest examination (31/136; 23%) than those in group 2 (17/179; 9%) (p=0.001).

There was no relationship between the GPs’ clinical assessment that an infection warranting antibiotics was present and bacterial or atypical infection being subsequently found (table 4).

Outcome and relation to evidence of infection and antibiotic use

Reconsultation for the same illness within a month was common, with nearly one in five patients arranging to see their GP again. Direct or indirect evidence of infection at first presentation did not relate to reconsultation, neither did antibiotic use when analysed for groups 1 and 2 as a whole nor for individual pathogens (table 5).

Of the 75 patients who had one or more atypical pathogens identified, 43 (57%) were prescribed an antibiotic (amoxycillin (34), erythromycin (7), a quinolone (2)). The outcome was not related to receiving an antibiotic to which an atypical infection should respond—that is, erythromycin or a quinolone.

Discussion

This study confirms that consultations for acute LRTi in adults are very common, particularly for younger women, probably reflecting a higher consulting habit for this group.

Case definitions: LRTi and “acute bronchitis”

Studies into acute respiratory illnesses have long struggled to define episodes in primary care where GPs almost invariably manage and prescribe without investigations.

We have defined a term “acute lower respiratory tract illness” similar to that used in previous studies. It approximates to the various definitions of “acute bronchitis” used before but has the important advantage of being definable, reproducible, and readily usable within a routine GP consultation.

Measuring outcome of acute respiratory infections

Defining a clinically relevant and easily measurable end point for many symptom complexes in primary care is difficult. We chose reconsultation as an outcome for this condition because it is: (a) common, with an incidence of 20–30%; (b) important, causing inconvenience to patients and their doctors and increased use of health service resources; (c) easy to measure accurately, and (d) related to persisting, bothersome symptoms. It therefore has more meaning than minor differences in recovery rates recorded on symptom diaries.

Study limitations

The study has a number of limitations. We were only able to investigate about two thirds of the patients who consulted during the winter period. Although demographic features were very similar, systemic and lower respiratory symptoms and antibiotic use were less common in the group not investigated in the winter, as were systemic symptoms in the summer group, suggesting milder illness. Our results may not be representative of the whole group but it is unlikely that we missed much serious illness.

Our GP practices may not be typical as they are experienced in research into LRTi and antibiotic use. The level of antibiotic prescribing was lower than typical levels in LRTi. It is possible that the patients in the practices consulted less frequently than average for minor lower respiratory symptoms, but this
also suggests that we are unlikely to have missed much significant infection associated with more serious illness. The aetiology study was only conducted over six winter months when viruses are more common. This may explain why systemic symptoms were more common in the patients who consulted in the winter. It also coincided with a four yearly cycle of mycoplasma infection. Care therefore needs to be taken in extrapolating the findings to the whole year.

### IDENTIFICATION OF PATHOGENS

There are few data regarding the role of bacterial and atypical infection in acute bronchitis. Previous studies have largely focused on viruses which occurred in about one quarter of patients. Melbye et al reported atypical pathogens in 5% of 393 previously well adults who consulted with both upper and lower respiratory symptoms. Only four of 67 patients with acute bronchitis had bacterial infection, all pneumococcal.

This study, the first using traditional and newer microbiological investigations, has shown that the symptoms of acute bronchitis, or similar definitions, in previously well adults are related to bacterial, atypical, and viral respiratory pathogens. Specimen collection and follow up in the community were excellent. The association between the detection of bacterial and atypical pathogens and raised CRP levels and chest radiographic changes, together with the marked seasonal pattern, suggest that the pathogens we detected were relevant to the acute illness, causing infection rather than just colonisation.

Bacterial pathogens were found in over 25% of patients with Streptococcus pneumoniae being the most common followed by Haemophilus influenzae and M catarrhalis. Atypical pathogens were as common as bacterial pathogens with C pneumoniae occurring in 17% and M pneumoniae in 7%. Viral pathogens, most commonly the influenza viruses, were found in one fifth of patients and were not infrequently associated with bacterial and atypical pathogens.

The bacteria we identified are those typically associated with community acquired lower respiratory tract infection (LRTI) and pneumonia. Ampicillin resistant bacterial pathogens were isolated from only five patients (H influenzae (2), M catarrhalis (3)), which suggests that antibiotic resistance is not a problem in this population and hence there is little need to use newer antibiotics such as fluoroquinolones.

Our study coincided with a national epidemic of mycoplasma, which explains the much higher incidence of this organism than we have previously reported for LRTI. Although this emphasises the importance of GPs knowing current seasonal trends in common infections, the use or choice of antibiotic did not relate to outcome in our study. Such up to date epidemiological information is available from the Public Health Laboratory Service website (www.phls.co.uk).

There are few data on C pneumoniae as a respiratory pathogen in Britain but studies elsewhere have implicated it in 5–15% of LRTI and pneumonia, and routine treatment with macrolides has been recommended. We have previously found C pneumoniae infection in 14% of adults with LRTI, a similar figure to the 17% we report here. In this study primary C pneumoniae infection was not associated with
indication for antibiotic treatment in a patient with acute lower respiratory tract symptoms. The association between focal chest signs on examination and chest radiographic changes supports our previous experience that these physical signs have some value in identifying patients who may have abnormal radiographs. However, it seems doubtful that an urgent chest radiograph in every previously well adult with acute lower respiratory tract symptoms is of any practical value in management as only 6% of the patients had radiographic pneumonia and about half of our patients with changes on the chest radiograph recovered without receiving antibiotics. In only two instances did the doctor call back the patient and institute antibiotic treatment after receiving the chest radiographic report; one of these patients also had persisting symptoms and signs. In a previous study we found that only 3% of patients treated for LRTI were recalled by their doctor because of the initial investigation results.

Guidelines for requesting a chest radiograph are being prepared for GPs to facilitate the early detection of lung cancer. Presentation with LRTI was not a useful pointer in this respect for our patients. A shadow suspicious of malignancy was reported on two chest radiographs but was not confirmed on subsequent investigations.

It has been suggested that rapid measurement of CRP levels may be a useful guide to bacterial infection and antibiotic therapy. We found that high CRP levels were related to bacterial or atypical infection but not to outcome, which suggests that knowing the result is unlikely to influence management and outcome. Indeed, it may paradoxically increase unnecessary antibiotic prescribing.

**OUTCOME IN RELATION TO PATHOGENS AND MANAGEMENT**

In this observational study the outcome did not relate to the presence of bacterial or atypical pathogens or to prescribing antibiotics to the patient and institute antibiotic treatment after receiving the chest radiographic report; one of these patients also had persisting symptoms and signs. In a previous study we found that only 3% of patients treated for LRTI were recalled by their doctor because of the initial investigation results.

which the pathogen should respond. We have previously found reconsultation not to relate to use of antibiotics at the index consultation.15 A systematic review of the role of antibiotics for acute bronchitis similarly concluded that, taken overall, antibiotics did little to influence the natural history of the symptoms and any minor benefit in individual groups was offset by side effects to the antibiotics.16

However, it is inappropriate and unhelpful to suggest that antibiotics will help no patients with acute bronchitis or LRTI,16 as there will clearly be a cohort of patients for whom antibiotics will be beneficial. The difficulty is in identifying such patients in the primary care setting and the challenge is to come up with practical and evidence based guidance that may be useful to the GP. Unfortunately our study did not find that, overall, clinical judgement or specific symptoms or signs related to outcome. However, the strong association between focal chest signs and radiographic pneumonia suggests that the practice of many GPs of prescribing antibiotics to patients with LRTI when such signs are present is well founded.2

In conclusion, this study has confirmed that LRTI is a very common reason for previously well adults to consult their GP and hence is a condition for which agreed management would be useful. LRTI is caused by infection. Bacterial, atypical, and viral pathogens can be identified in more than half the cases and indirect evidence of infection in a quarter. With the exception of focal chest signs, neither the findings on physical examination nor the GP’s global assessment reliably identifies patients with evidence of infection. The usual practice of undertaking few routine investigations appears well founded. Our observations on the outcome of LRTI supports the view that antibiotics generally, or even when directed specifically at particular pathogens, do not influence the outcome in most patients, most of whom will recover spontaneously.

We are most grateful to the following who all contributed to the success of the study in different ways: Peter Parvin, Suresh Patel, Richard Howard, Mike Elliott, Gina Bajek, Fiona McCracken, Jacqueline Pedcock and Andrew Flewitt (general practitioners), Loraine Harles, Christina Rooebuck and Elisabeth Everitt (research practice nurses), Sallie Porter and Denise Clegg (practice managers) and their staff, Robert Cave and Joanne Patryman at Nottingham Public Health Laboratory, Stephanie Elden in Leicester, and Anna Jaakkola in Finland who coordinated the microbiology specimens, and Dr Margaret Sillis, Euden in Leicester, and Anna Jaakkola in Finland who coordinated the microbiology specimens for the study. The study was supported by a project grant from the British Lung Foundation and the Co-operative Insurance Society of Macfarlane.

Conflict of interest: none.
