Chronic obstructive pulmonary disease c2: Pathology and biochemistry of emphysema

J C Hogg, R M Senior

The pathology and pathogenesis of emphysema are reviewed, with particular reference to the proteinase-antiproteinase hypothesis.

PATHOLOGY

The seminal work of McLean and Leopold and Gough established that centrilobular emphysema (CLE) is the result of dilatation and destruction of the respiratory bronchioles (Fig 1). Subsequent studies showed that these lesions are larger and more numerous in the upper lung.

The term "focal emphysema" was introduced to describe a form of lung destruction in the periphery of the lobule along the lobular scar. This definition was modified to include "destruction of alveolar walls without obvious fibrosis". McLean and Leopold and Gough implicated the inflammatory response in the pathogenesis of the centrilobular form of emphysema, but this suggestion was interpreted conservatively because their studies were based on necroscopic specimens that were frequently contaminated by terminal bronchopneumonia.

Panlobular or panacinar emphysema (PLE) results from a more uniform destruction of all of the acini within the secondary lobule. Thurlbeck showed that, in its mildest forms, it is difficult to discern PLE from normal lung unless the lung is fixed in full inflation and carefully examined using low power magnification. In contrast to the centrilobular lesion, panacinar emphysema is more severe in the lower lobes but a predominant lower lobe distribution only becomes statistically significant in severe disease. Panacinar emphysema is commonly associated with α1-antitrypsin deficiency, but is also found in cases where no clearcut genetic abnormality has been identified.

Distal acinar, mantle, and paraseptal emphysema are terms used to describe lesions that occur in the periphery of the lobule along the lobular septae, particularly in the subpleural region. Localised paraseptal emphysema has been associated with spontaneous pneumothorax in young adults and bullous lung disease in older individuals where individual large cysts may interfere with lung function. Unilateral emphysema or McLeod's syndrome occurs as a complication of severe childhood infections caused by rubella or adenovirus, and congenital lobar emphysema is a developmental abnormality affecting newborn children. The emphysema that forms around scars lacks any special distribution in the lobule and is referred to as irregular emphysema.

Leukocyte kinetics in the lung

Leukocyte accumulation in the lung is a feature of emphysema (see below). The traffic of leukocytes through the lung microvessels and their migration out of the vascular space through the tissue and into the airspaces is incompletely understood. The pulmonary circulation receives the entire output of the right ventricle—that is, ∼6 l/min or 8600 l blood in 24 hours. As each litre of blood contains 10^{12} leukocytes, the lung receives approximately 8.6 × 10^{10} leukocytes every 24 hours. The bronchial circulation adds approximately 1% of the left ventricle output to this value and this increases in disease. The neutrophils are the easiest to keep track of because they do not divide after they enter the pulmonary circulation from the bone marrow, normally remain inside the vascular space, and do not re-enter the circulation after they migrate out of the microvasculature.

The maximum diameter of the circulating cells is slightly larger than the average capillary but, because the disc shaped erythrocytes are able to fold, they are much more deformable than the spherically shaped leukocytes. This allows erythrocytes to move through restrictions in lung capillaries much more quickly than leukocytes, and the multisegmented nature of the lung capillary bed allows the faster moving erythrocytes to pass the slower moving neutrophils. This difference between erythrocyte and leukocyte transit time concentrates the neutrophils with respect to the erythrocytes in the lung capillaries and accounts for the so-called margination pool of neutrophils in the pulmonary circulation. Cigarette smoking increases the number of marginated neutrophils in the lung capillary bed. Only a very small proportion of circulating neutrophils delivered to the lung ever migrate out of the vascular space, even in the presence of strong stimuli such as pneumococcal pneumonia.

Walker and colleagues have shown that the surface of interstitial fibroblasts form a network that guides the neutrophil from its point of exit out of the capillary to the point of entry into the alveolar airspace. Their work suggests an important interaction between the leukocytes and the...
The idea that emphysema results from chronic inflammation affecting alveoli and terminal airways has dominated this field ever since the discovery linking emphysema and α1-antitrypsin deficiency to neutrophil elastase (NE). Because NE is expressed almost exclusively by neutrophils, and because smokers have more neutrophils in their bronchoalveolar lavage (BAL) fluid than non-smokers, neutrophils have long been considered a major culprit in causing emphysema. However, macrophages, T lymphocytes, and eosinophils are increasingly being implicated in the pathogenesis of lung destruction in emphysema, and some data even suggest that the presence of neutrophils in alveolar walls in smokers correlates with preservation rather than destruction of alveolar walls. A recent analysis of inflammatory cells in the lung parenchyma and terminal airspaces in surgically resected lungs having no emphysema, mild emphysema, or severe emphysema found increased numbers of neutrophils, macrophages, T lymphocytes, and eosinophils in emphysematous tissue. The numbers of each inflammatory cell type correlated equally well with the severity of emphysema so that, by cell numbers, no one type of inflammatory cell appeared to predominate. Compared with normal lung, lungs with severe emphysema contained approximately 10 times more of each of the inflammatory cell types. These results show that a complex inflammatory response exists in the emphysematous lung. Precisely how the various processes appear to be involved in the pathogenesis of emphysema associated with cigarette smoking remains unsettled. Gelatinase B (MMP-9), for example, has been implicated in some studies, but neutrophils appear to enter tissues normally in gelatinase B-deficient mice.

What cells are responsible for ECM degradation in emphysema? Mouse models have been informative about mechanisms of emphysema and, at times, emphysema has been an unexpected finding in genetically abnormal mice.
inflammatory cell types contribute to the destruction of alveolar walls is yet to be determined, but a reasonable speculation would be that neutrophils, macrophages, and eosinophils degrade alveolar ECM directly by releasing proteinases whereas T lymphocytes influence inflammatory cell recruitment and the function of inflammatory cells that release proteinases. The remarkable expansion of the alveolar macrophage population in many smokers’ lungs may be important in producing alveolar destruction, even though proteinase release per cell may be similar between smokers with emphysema and smokers who do not have emphysema.

An intriguing feature of these recent data is that the markedly increased number of inflammatory cells in severe emphysema was present even in individuals who had stopped smoking years earlier. This finding fits with the clinical situation of progressive deterioration of lung function among some former smokers with COPD. The mechanisms that perpetuate recruitment of inflammatory cells in lung tissue long after the primary stimulus—namely, cigarette smoke—has been removed are not known, but peptides derived from ECM are chemotactic for inflammatory cells which suggests that destruction of ECM may be self-perpetuating.

Inflammatory cells may not be the only source of proteinases that degrade alveolar septal ECM. Alveolar epithelial cells in lungs removed for lung transplantation for COPD and in lung tissues resected at lung volume reduction surgery express the collagenase matrix metalloproteinase 1 (MMP-1) mRNA and protein, and exhibit collagenase activity. Similarly, in guinea pigs exposed to cigarette smoke, MMPs are expressed by lung structural cells. However, it is important to note that expression of MMPs by alveolar epithelium or other structural cells does not necessarily lead to emphysema as it also occurs in interstitial lung diseases.

While intrapulmonary inflammation appears to be a consistent feature of smoking and emphysema, three recent studies in rodents illustrate that emphysema can develop with minimal or no inflammation. Rats exposed to agents that interfere with the function of vascular endothelial growth factor (VEGFR) receptors have apoptosis of alveolar epithelial cells and capillary endothelial cells and develop emphysema-like lungs. TIMP-3 “knockout” mice undergo pathological alveolar enlargement beginning around 2 weeks postpartum without an increase in inflammatory cells. A single intratracheal instillation of β-D-xyloside in rats is followed by disturbed proteoglycan synthesis, parenchymal destruction, and airspace enlargement comparable to that attained with intratracheal pancreatic elastase and it occurs without inflammation. The relevance of these models to human emphysema is not clear, but the models suggest that diverse homeostatic mechanisms are required to preserve normal lung structure.

What proteinases are responsible for alveolar septal destruction in emphysema?

The diversity of inflammatory cell types in emphysematous tissue and the variety of proteinases produced by these cells raise the strong possibility that many proteinases might be involved in emphysematous lung destruction. This diversity also suggests that there might be differences between individuals and even in the same individual at different times. With the exception of emphysema associated with α1-antitrypsin deficiency, in which NE appears to be the critical proteinase, conclusively identifying the key enzymes in emphysema pathogenesis has proved difficult. The present brief discussion will focus on neutrophil elastase and MMPs because these are the proteinases most associated with emphysema.

The possibility that NE is important in emphysema even among smokers with normal levels of α1-antitrypsin has considerable support. For example, smoking increases NE in BAL fluid, and smokers with CT scan evidence of emphysema have higher levels of neutrophil specific proteinases including NE in their BAL fluid than smokers without emphysema. The role of NE in causing emphysema may be principally via its capacity to degrade the elastin in elastic fibres, but other mechanisms may also operate. Mice lacking NE as a result of
gene targeting show some protection from cigarette smoke induced emphysema caused by decreases in alveolar recruitment of neutrophils and monocytes, macrophage elastase activation, and degradation of TIMP-1, an inhibitor of macrophage elastase.66

Over the past few years MMPs have gained support as pro-

teases involved in alveolar destruction in emphysema as the family of enzymes is associated with both physiological and pathological remodelling in many tissues including the lung.37 As a group, MMPs can degrade all components of the ECM. Members of the MMP family of enzymes are present in low to undetectable levels in normal lung, but are readily detected in many lung diseases. Macrophages can synthesise several MMPs. In contrast, neutrophils do not synthesise MMPs once they have completed their development in the bone marrow, but they carry in their granules two MMPs—MMP-2 (neutrophil collagenase) and MMP-9 (gelatinase B). It is important to note that the expression of MMPs is not restricted to inflammatory cells; virtually all cells including alveolar epithelial cells and fibroblasts can make MMPs. Also, the potential substrates of MMPs are not limited to ECM as many other proteins, including α1-antitrypsin, are also cleaved by these enzymes.38

Several MMPs have been implicated in the pathogenesis of emphysema (table 1). Interpretation of these data is difficult, however, because (1) most of them comes from moderate or advanced emphysema, (2) different types of samples have been analysed ranging from BAL fluid, alveolar macrophages in culture, to surgically resected lung tissue, and (3) the types of MMP measurements have been diverse, varying from enzymatic activity to immunological assays so that the issue of pro-enzymes versus active forms is not clear. Moreover, studies of MMP production; and

• M MP-12 (macrophage elastase) is not prominent in human emphysema even though it is critical for smoking induced emphysema in the mouse.39

As shown in table 1, the MMPs associated with emphysema include the collagenases MMP-1, which is typically produced by fibroblasts, and MMP-8 which is found primarily in neutrophils. Because alveolar septal collagen turnover appears to occur in emphysema (see below), it would not be surprising if MMP-1 and MMP-8 have a role in alveolar septal destruction. Guinea pigs with cigarette smoke induced emphysema show collagen mRNA and collagenase protein in alveolar macrophages, alveolar epithelial and interstitial cells, and have collagenase activity in lung homogenates, unlike lungs from control animals.40

Also associated with emphysema are the so-called gelat-

i nases MMP-2 and MMP-9. These proteases degrade a number of ECM components, including type IV collagen and elastin.38 Neutrophils contain abundant MMP-9 that is readily released when the cells are stimulated. A polymorphism in the promoter of MMP-9 has been associated with an increased incidence of emphysema among smokers of comparable age (∼65 years) and smoking history (∼60 pack years).41 Increases in MMP-14 (also called MT-1 M MP) found in one study are intriguing,42 as this proteinase has a key role in the activation of MMP-2 in a process that occurs on cell surfaces.

Human alveolar macrophages make MMP-12 (also called macrophage elastase),43 but its production appears to be less relative to other MMPs and much less than murine macrophages. This difference, and the fact that MMP-12 has not been found in several studies,42 suggests that, with regard to this enzyme, the mouse and human differ.

What alveolar septal ECM component(s) are targets in the pathogenesis of emphysema?

Many of the early experimental studies supporting the proteinase-antiproteinase hypothesis pointed to elastin as the critical target of proteinases that cause emphysema.44 Indeed, this emphasis was so dominant that the hypothesis has also been labelled the “elastase-antielastase” hypothesis.45 Clearly, destruction of alveolar elastin does lead to emphysema experimentally and frayed elastic fibres are evident in alveolar tissue in human emphysema.46 However, focus on the importance of elastic fibres has obscured the fact that destruction of alveolar walls affects other ECM components, of which collagen is the most prominent quantitatively and morphologically. Interestingly, when experiments involving intratracheal instillation of enzymes to produce emphysema were in vogue a few decades ago, none was done with mammalian collagenase nor have such experiments been done yet.

Experimental studies as well as examinations of human tissue point to collagen breakdown and resynthesis in emphysema.47 The likelihood that collagen turnover is a feature of the pathogenesis of emphysema is underscored by the prevalence of increased collagenolytic enzymes in human emphysema (table 1) and a small body of experimental data.48 Reductions in lung collagen can occur quickly in response to exposure to cigarette smoke, as increased levels of collagenous peptides are present in the BAL fluid of mice within 1 day of exposure to smoke from two cigarettes.49 However, with chronic exposure in mice there is increased lung collagen concurrent with the development of emphysema,50 results that match observations of increased lung collagen

| Table 1 Matrix metalloproteinases (MMPs) in human emphysema |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| Author (ref)    | Emphysema       | Test samples    | Observations    | Comments         |
| Finlay51        | CT AM mRNA and culture media | ↑ collagenase 1 (MMP-1) ↑ gelatinase B (MMP-9) | No increase in expression of macrophage elastase (MMP-12) | MMs probably neutrophil derived |
| Finlay51        | CT BAL fluid    | ↑ collagenase activity ↑ gelatinase B (MMP-9) | No increase in expression of macrophage elastase (MMP-12) | MMs in BAL fluid from inflammatory cells; no ↑ gelatinase B (MMP-9) in AM culture media in emphysema |
| Ohnishi40       | Histology Lung tissue from LVRS | ↑ collagenase 1, 2, 3 (MMP-1, -8, -13) ↑ gelatinases A, B (MMP-2, -9) | Collagenase expressed by type II cells. No increase in expression of macrophage elastase (MMP-12) | This polymorphism also associated with an increased incidence of coronary atherosclerosis |
| Betsuyaku41     | CT BAL fluid and AM culture media | ↑ collagenase 2 (MMP-8), ↑ gelatinase B (MMP-9) | MMs are expressed by both inflammatory cells and structural cells of the lung |
| Segura-Valdez42 | Histology Lung tissue from autopsy and LVRS; BAL fluid | ↑ collagenase 1 (MMP-1) | Collagenase expressed by type II cells. No increase in expression of macrophage elastase (MMP-12) | This polymorphism also associated with an increased incidence of coronary atherosclerosis |
| Imai25          | Histology Lung tissue from lung transplant and LVRS | ↑ gelatinase B (MMP-9) polymorphism in smokers with emphysema | |
| Minematsu43     | CT Cellular DNA | | |

content in human emphysema. Clearly, emphysema involves more than elastin degradation. Indeed, it is likely that the lung remodelling recognised as emphysema involves destruction and synthesis of all components of the lung ECM.
