The value of multiple tests of respiratory muscle strength

Thorax 2007;62:975–980. doi: 10.1136/thx.2006.072884

Background: Respiratory muscle weakness is an important clinical problem. Tests of varying complexity and invasiveness are available to assess respiratory muscle strength. The relative precision of different tests in the detection of weakness is less clear, as is the value of multiple tests.

Methods: The respiratory muscle function tests of clinical referrals who had multiple tests assessed in our laboratories over a 6-year period were analysed. Thresholds for weakness for each test were determined from published and in-house laboratory data. The patients were divided into three groups: those who had all relevant measurements of global inspiratory muscle strength (group A, n = 182), those with full assessment of diaphragm strength (group B, n = 264) and those for whom expiratory muscle strength was fully evaluated (group C, n = 60). The diagnostic outcome of each inspiratory, diaphragm and expiratory muscle test, both singly and in combination, was studied and the impact of using more than one test to detect weakness was calculated.

Results: The clinical referrals were primarily for the evaluation of neuromuscular diseases and dyspnoea of unknown cause. A low maximal inspiratory mouth pressure (PImax) was recorded in 40.1% of referrals in group A, while a low sniff nasal pressure (Sniff Pnasal) was recorded in 41.8% and a low sniff oesophageal pressure (Sniff Poes) in 37.9%. When assessing inspiratory strength with the combination of all three tests, 29.6% of patients had weakness. Using the two non-invasive tests (PImax and Sniff Pnasal) in combination, a similar result was obtained (low in 32.4%). Combining Sniff Pdi (low in 68.2%) and Twitch Pdi (low in 67.4%) reduced the diagnoses of patients with diaphragm weakness to 55.3% in group B. 38.3% of the patients in group C had expiratory muscle weakness as measured by maximum expiratory pressure (PEmax) compared with 36.7% when weakness was diagnosed by cough gastric pressure (Pgas), and 28.3% when assessed by Twitch T10. Combining all three expiratory muscle tests reduced the number of patients diagnosed as having expiratory muscle weakness to 16.7%.

Conclusion: The use of single tests such as PImax, PEmax and other available individual tests of inspiratory, diaphragm and expiratory muscle strength tends to overdiagnose weakness. Combinations of tests increase diagnostic precision and, in the population studied, they reduced the diagnosis of inspiratory, specific diaphragm and expiratory muscle weakness by 19–56%. Measuring both PImax and Sniff Pnasal resulted in a relative reduction of 19.2% of patients falsely diagnosed with inspiratory muscle weakness. The addition of Twitch Pdi to Sniff Pdi increased diagnostic precision by a smaller amount (18.9%). Having multiple tests of respiratory muscle function available both increases diagnostic precision and makes assessment possible in a range of clinical circumstances.

Measurement of respiratory muscle strength is clinically useful in the assessment of selected patients, most commonly those with neuromuscular diseases or unexplained breathlessness.1 2

Maximum inspiratory (Pmax) and expiratory (Pemax) pressures are most frequently measured. Pmax and PEmax are simple quick tests, and high values exclude clinically significant weakness. However, low values are common and may reflect poor technique or effort rather than muscle weakness.3

Additional tests are available which are likely to improve diagnostic precision but are more complex and invasive.4 5 We have reviewed our test results in patients referred for assessment of respiratory muscle strength to determine the value of multiple respiratory muscle tests. We hypothesised that multiple tests might reduce the number of patients erroneously diagnosed as having muscle weakness.

METHODS

Test results of clinical referrals made to the respiratory muscle laboratories of King’s College and Brompton Hospitals between 2000 and 2006 were analysed. Tests were undertaken according to established methods as described in the ATS/ERS joint statement.1 The following tests were used.

Maximum inspiratory pressure (Pmax)

Maximum inspiratory pressures were measured from functional residual capacity in the standard way4 5 with the patient seated, wearing a nose-clip and using a flanged mouthpiece (P K Morgan Ltd, Rainham, UK). Repeated efforts were made until consistent results were achieved and the numerically largest pressure noted. The average of the pressure was measured over 1 s.4

Several publications report normal values using a flanged mouthpiece.6-12 Weakness was defined as the mean normal value minus 1.96 standard deviations based on the study by Wilson et al (table 1).7 This number reflects the 100% line in the figures in the Results section.

Sniff manoeuvres

Balloon catheters for the measurement of pressure (Cooper Surgical, Connecticut, USA) lubricated with 2% lidocaine gel were introduced via one nostril into the oesophagus and stomach as described by Baydur et al.13 The distal balloon (filled

Abbreviations: Pdi, transdiaphragmatic pressure; Pmax, maximum inspiratory pressure; Pgas, gastric pressure; Pmax, maximum inspiratory pressure; Pnasal, nasal pressure; Poes, oesophageal pressure
Sniff oesophageal pressure (Sniff Poes)

Sniff manoeuvres were performed with the patient seated and the balloon catheters in place as described above. At least 5–10 maximal sniffs were measured and the largest numerical pressure was noted. Data of Laroche et al6 were used to calculate the normal cut off values (table 1).

Sniff nasal pressure (Sniff Pnasal)

A plug, used to obstruct one nostril, incorporated the distal 2–3 cm of a 30 cm polyethylene catheter with a 2.0 mm internal diameter (Intersurgical Scientific Instruments, Oxford, UK). The proximal end of the catheter was attached to a pressure transducer (Validyne, Northridge, California, USA). The mean minus 1.96 standard deviations was calculated and the parameter retransformed (1/y) to give the cut off value corresponding to normal cut off values for each respiratory muscle test (table 1). 6

Sniff transdiaphragmatic pressure (Sniff Pdi)

Pressure catheters were placed and maximal sniff manoeuvres performed as described above. The highest numerical pressure of 5–10 constant sniffs was taken. Normal cut off values refer to the data of Miller et al6 who described normal values for the sniff Pdi test (table 1).

Twitch transdiaphragmatic pressure (Twitch Pdi)

Twitch transdiaphragmatic pressure was measured following magnetic stimulation of the phrenic nerves via a bilateral anterolateral approach at functional residual capacity. 6 14 15 The patient was seated, wearing a noseclip, and the mouth was closed. For magnetic stimulation a Magstim 200 (Magstim Co Ltd, Whitland, UK) with a 43 mm double coil (P/N9784-00; Magstim Co Ltd) was used. After achieving a supermaximal stimulus, at least five consistent twitches were recorded and the average Twitch Pdi calculated.

Luo et al investigated twitch Pdi in normal subjects and found it to be 28 (5) cm H2O (table 1). 6 No distinction was made for normal values between the sexes because the available literature on sex differences is insufficient.

Maximum expiratory pressure (PEmax)

Maximum expiratory pressures were measured from total lung capacity in the standard way with the patient seated, wearing a noseclip and using a flanged mouthpiece (P K Morgan Ltd). 3 Several studies have reported normal values using a flanged mouthpiece.19–22 Normal cut off values refer to the study of Wilson et al (table 1). 5

Cough gastric pressure (Cough Pgas)

Pressure balloons were positioned as described above for sniff manoeuvres. The cough manoeuvre was performed as previously reported, breathing in deeply first, with the patient seated and wearing a noseclip. Coughs were repeated at least 5–10 times until consistent measurements were achieved. The numerically highest value was taken, measuring from relaxed end-expiratory baseline gastric pressure to peak pressure during the cough. Man et al23 described cough gastric pressures in 99 healthy volunteers, enabling normal cut off values to be calculated (table 1).

Twitch T10 gastric pressure (Twitch T10)

Gastric pressure was measured as described for sniff manoeuvres and magnetic stimulation of the thoracic nerve roots was performed with a 90 mm circular coil (P/N9784-00; Magstim Co Ltd) placed with its centre over the 10th thoracic vertebra in the mid line.16 The manoeuvre was undertaken at functional residual capacity with the patient seated, wearing a noseclip and the mouth closed. Twitches were repeated at least 5–10 times until consistent measurements were obtained and an average Twitch T10 was calculated. There are few normal data reported for this test. Our laboratory data are from 65 normal subjects (41 men and 24 women) of mean (SD) age 51 (16) years and body mass index 25.6 (3.6) kg/m2. The results are not normally distributed but are positively skewed. The median was 39.4 cm H2O (interquartile range 26.6 cm H2O). The cut off value for weakness was calculated after transformation of the data into a log-normal distribution (mean 1.6 (0.20)). The mean minus 1.96 standard deviations was calculated and the parameter retransformed (1/y) to give the cut off value in table 1. As for Twitch Pdi, no distinction was made between sexes because of the relatively limited data.

The outcome of the respiratory muscle tests in diagnosing weakness was studied singly and in combination. Cross-tabulation identified the diagnosis of weakness for each test and the added value of using more than one test in detecting respiratory muscle weakness was determined.

Analysis of data

For the purposes of analysis, patient data were used for comparison only if all of the global inspiratory, specific diaphragm or expiratory muscle tests were performed. For inspiratory muscle tests (PImax, Sniff Pnasal and Sniff Poes) this was 182 of the referrals (group A), for diaphragm specific
tests (Sniff Pdi and Twitch Pdi) 264 (Group B), and for expiratory muscle tests (PImax, Cough Pgas and Twitch T10) 60 (Group C). Individual test results were judged relative to the

weakness when assessed by PEmax. When assessed by cough Pgas, 36.7% of the patients had low values and, with Twitch T10, 28.3% of the patients were considered to be weak. The

Diaphragm strength tests (Group B)

One hundred and eighty-two patients completed all inspiratory muscle tests (Pmax, Sniff Pnasal and Sniff Poes, fig 1). Pmax was low in 40.1%, Sniff Pnasal in 41.8% and Sniff Poes in 37.9%. The correlation coefficient between Pmax and Sniff Pnasal was \( r = 0.74 \) (\( p < 0.01 \), fig 1), between Pmax and Sniff Poes was \( r = 0.73 \) (\( p < 0.01 \), fig 1) and between Sniff Pnasal and Sniff Poes was \( r = 0.90 \) (\( p < 0.01 \), fig 1). Cross-tabulation (table 6) shows the numbers of patients with low or normal results in all of the tests. Combining the results for the three tests of global inspiratory muscle strength gave a diagnosis of weakness in 29.1% (table 7). This is a relative reduction of 27.4% compared with Pmax alone. Using two non-invasive tests (Pmax and Sniff Pnasal) in combination gave a similar result (low in 32.4%).

Expiratory muscle tests (Group C)

For expiratory muscle strength tests, data from 60 patients who completed measurement of cough Pgas, Twitch T10 and PImax were analysed: 38.3% of the patients had expiratory muscle weakness when assessed by PImax. When assessed by cough Pgas, 36.7% of the patients had low values and, with Twitch T10, 28.3% of the patients were considered to be weak. The correlation between PImax and cough Pgas was \( r = 0.61 \) (\( p < 0.01 \), fig 3); between PImax and Twitch T10 \( r = 0.28 \) (\( p = 0.03 \), fig 3) and between cough Pgas and Twitch T10 \( r = 0.63 \) (\( p < 0.01 \), fig 3). The combination of all three tests of expiratory muscle strength yielded a diagnosis of weakness in 16.7% (tables 6 and 9), a relative reduction of 56.4% compared with Pmax alone.

RESULTS

The most common reason for referral was to investigate neuromuscular diseases and the cause of breathlessness (tables 2 and 3). Data on age, sex and lung function for the three groups are shown in table 4 and the results of the respiratory muscle tests are shown in table 5.

Global inspiratory muscle tests (Group A)

For tests of diaphragm function the 264 clinical referrals who had both Sniff Pdi and Twitch Pdi measurements were analysed (table 5); 68.2% had weakness when assessed by Sniff Pdi, and 67.4% when Twitch Pdi was measured. Between Sniff Pdi and Twitch Pdi was \( r = 0.57 \) (\( p = 0.01 \), fig 1) and between Sniff Pdi and Twitch Pdi (tables 6 and 8), a relative reduction of 18.9% compared with Sniff Pdi alone.

Diaphragm strength tests (Group B)

For tests of diaphragm function the 264 clinical referrals who had both Sniff Pdi and Twitch Pdi measurements were analysed (table 5); 68.2% had weakness when assessed by Sniff Pdi, and 67.4% when Twitch Pdi was measured. Between Sniff Pdi and Twitch Pdi was \( r = 0.57 \) (\( p = 0.01 \), fig 1) and between Sniff Pdi and Twitch Pdi (tables 6 and 8), a relative reduction of 18.9% compared with Sniff Pdi alone.

Expiratory muscle tests (Group C)

For expiratory muscle strength tests, data from 60 patients who completed measurement of cough Pgas, Twitch T10 and PImax were analysed: 38.3% of the patients had expiratory muscle weakness when assessed by PImax. When assessed by cough Pgas, 36.7% of the patients had low values and, with Twitch T10, 28.3% of the patients were considered to be weak. The correlation between PImax and cough Pgas was \( r = 0.61 \) (\( p < 0.01 \), fig 3); between PImax and Twitch T10 \( r = 0.28 \) (\( p = 0.03 \), fig 3) and between cough Pgas and Twitch T10 \( r = 0.63 \) (\( p < 0.01 \), fig 3). The combination of all three tests of expiratory muscle strength yielded a diagnosis of weakness in 16.7% (tables 6 and 9), a relative reduction of 56.4% compared with Pmax alone.

RESULTS

The most common reason for referral was to investigate neuromuscular diseases and the cause of breathlessness (tables 2 and 3). Data on age, sex and lung function for the three groups are shown in table 4 and the results of the respiratory muscle tests are shown in table 5.

Global inspiratory muscle tests (Group A)

One hundred and eighty-two patients completed all inspiratory muscle tests (Pmax, Sniff Pnasal and Sniff Poes, fig 1). Pmax was low in 40.1%, Sniff Pnasal in 41.8% and Sniff Poes in 37.9%. The correlation coefficient between Pmax and Sniff Pnasal was \( r = 0.74 \) (\( p < 0.01 \), fig 1), between Pmax and Sniff Poes was \( r = 0.73 \) (\( p < 0.01 \), fig 1) and between Sniff Pnasal and Sniff Poes was \( r = 0.90 \) (\( p < 0.01 \), fig 1). Cross-tabulation (table 6) shows the numbers of patients with low or normal results in all of the tests. Combining the results for the three tests of global inspiratory muscle strength gave a diagnosis of weakness in 29.1% (table 7). This is a relative reduction of 27.4% compared with Pmax alone. Using two non-invasive tests (Pmax and Sniff Pnasal) in combination gave a similar result (low in 32.4%).

Diaphragm strength tests (Group B)

For tests of diaphragm function the 264 clinical referrals who had both Sniff Pdi and Twitch Pdi measurements were analysed (table 5); 68.2% had weakness when assessed by Sniff Pdi, and 67.4% when Twitch Pdi was measured. Between Sniff Pdi and Twitch Pdi was \( r = 0.57 \) (\( p = 0.01 \), fig 1) and between Sniff Pdi and Twitch Pdi (tables 6 and 8), a relative reduction of 18.9% compared with Sniff Pdi alone.

Expiratory muscle tests (Group C)

For expiratory muscle strength tests, data from 60 patients who completed measurement of cough Pgas, Twitch T10 and PImax were analysed: 38.3% of the patients had expiratory muscle weakness when assessed by PImax. When assessed by cough Pgas, 36.7% of the patients had low values and, with Twitch T10, 28.3% of the patients were considered to be weak. The correlation between PImax and cough Pgas was \( r = 0.61 \) (\( p < 0.01 \), fig 3); between PImax and Twitch T10 \( r = 0.28 \) (\( p = 0.03 \), fig 3) and between cough Pgas and Twitch T10 \( r = 0.63 \) (\( p < 0.01 \), fig 3). The combination of all three tests of expiratory muscle strength yielded a diagnosis of weakness in 16.7% (tables 6 and 9), a relative reduction of 56.4% compared with Pmax alone.

RESULTS

The most common reason for referral was to investigate neuromuscular diseases and the cause of breathlessness (tables 2 and 3). Data on age, sex and lung function for the three groups are shown in table 4 and the results of the respiratory muscle tests are shown in table 5.
DISCUSSION

PImax and PEmax are widely used, easily applied and non-invasive bedside tests. In our study, PImax and PEmax diagnosed weakness in 40.1% and 38.2%, respectively. However, the tests require maximal effort, coordination and cooperation and low values are common and difficult to interpret with confidence.34 Sniff Pnasal achieves similar results to PImax, and Sniff Poes—while more precise—is invasive. Compared with Sniff Pnasal, Sniff Poes reduces the diagnosis of weakness by about 10%. The combination of the two non-invasive tests (PImax and Sniff Pnasal) reduces the diagnosis of weakness by about 20% compared with either test alone. It is of interest that, by performing all three tests, the increase in diagnostic precision is around 30% compared with PImax or Sniff Pnasal alone, but they are not significantly better than the combination of PImax and Sniff Pnasal. Thus, for patients who are able to sniff and in whom there is likely to be good transmission of intrathoracic pressures (no nasal obstruction or airways obstruction), the combination of the

Combination of Pmax, Sniff Pnasal and Sniff Poes results reduces diagnosis of global inspiratory weakness to 29.1%. This is a relative reduction of 27.4% compared with Pmax alone, 30.4% reduction compared with Sniff Pnasal alone and 23.2% reduction compared with Sniff Poes alone. A combination of two tests (4 and 5) reduced the rate to 32.4% and 29.7%, respectively. There was no significant difference between the single tests. Performing all three tests achieved the highest precision.

care, and the Twitch technique also allows the separate evaluation of each hemidiaphragm. Furthermore, the combination of Sniff Pdi and Twitch Pdi is more precise than either test alone, reducing the relative risk of a false diagnosis of weakness by almost 20%.

The validity of cut-off values is important. Tests of respiratory muscle strength can either show normal or low results. A low test result means that the patient is weak as judged by this single test. The different cut-off points for each test were taken from the appropriate literature. We compared the published data most appropriate to the methods used at King's College Hospital and Royal Brompton Hospital. The cut-off for a normally distributed population was taken for all tests (except the non-normally distributed Twitch T10) by subtracting 1.96SD from the mean for a normal population. This definition is widely accepted for creating cut-off values and defining “abnormality”. We adopted a similar approach for all tests except Twitch T10 for which the only data available are our own laboratory values. The number of normal subjects for each test reported in the literature is substantial and reproducibility is well described, although we acknowledge that future studies of Twitch T10 will be useful to supplement our own results from 65 normal subjects.

One limitation of this study is a lack of sufficient normal data on the non-volitional tests used to assess diaphragm strength (Twitch Pdi) and expiratory muscle strength (Twitch T10), which does not allow a distinction between reference values for different sexes. More data are needed for Twitch Pdi and Twitch T10 to establish normal values for men and women. Combining male and female data inevitably reduces the sensitivity of the

SE, standard error of the mean; CI, confidence interval; Pdi, transdiaphragmatic pressure.

The combination of Sniff Pdi and Twitch Pdi diagnosed 55.3% of patients as having diaphragm weakness. The two tests combined reduced the diagnosis of diaphragm weakness by 18.9% compared with Sniff Pdi alone and 18.0% compared with Twitch Pdi alone.
A non-invasive combination of PImax and Sniff Pnasal is most clinically relevant and the good diagnostic performance for diagnosing weakness. The relative paucity of Twitch T10 data reduces—but does not negate—the considerable value of Twitch T10 as an inspiratory muscle test. Combining Twitch T10 results with other voluntary tests is helpful as some patients are less good at voluntary tests, but tests for diagnosing weakness. The relative paucity of Twitch T10 data reduces—but does not negate—the considerable value of Twitch T10 as an inspiratory muscle test.

In summary, the outcome of any one test of inspiratory, specific diaphragm or expiratory muscle strength is broadly similar to any other test. However, a combination of tests can substantially increase the precision of the diagnosis. In many patients it is the assessment of inspiratory muscle strength that is most clinically relevant and the good diagnostic performance of the non-invasive combination of Pmax and Sniff Pnasal is important.
