COPD and cancer mortality: the influence of statins

Y R B M van Gestel,1 S E Hoeks,1 D D Sin,2 V Hüzér,3 H Stam,4 F W Mertens,4 R T van Domburg,3 J J Bax,5 D Poldermans1

ABSTRACT

Background: Chronic obstructive pulmonary disease (COPD) is associated with an increased risk of lung cancer, independently of smoking. However, the relationship between COPD and total cancer mortality is less certain. A study was undertaken to investigate the association between COPD and total cancer mortality and to determine whether the use of statins, which have been associated with cancer risk in other settings, modified this relationship.

Methods: The study included 3371 patients with peripheral arterial disease who underwent vascular surgery between 1990 and 2006; 1310 (39%) had COPD and the rest did not. The primary end point was cancer mortality (lung and extrapulmonary) over a median follow-up of 5 years.

Results: COPD was associated with an increased risk of both lung cancer mortality (hazard ratio (HR) 2.06; 95% CI 1.32 to 3.20) and extrapulmonary cancer mortality (HR 1.43; 95% CI 1.06 to 1.94). The excess risk was mostly driven by patients with moderate and severe COPD. There was a trend towards a lower risk of cancer mortality among patients with COPD who used statins compared with patients with COPD who did not use statins (HR 0.57; 95% CI 0.32 to 1.01). Interestingly, the risk of extrapulmonary cancer mortality was lower among statin users with COPD (HR 0.49; 95% CI 0.24 to 0.99).

Conclusions: COPD was associated with increased lung and extrapulmonary cancer mortality in this large cohort of patients with peripheral arterial disease undergoing vascular surgery. The risk of lung cancer mortality increased with progression of COPD. Statins were associated with a reduced risk of extrapulmonary cancer mortality in patients with COPD.

COPD is a worldwide epidemic, affecting 10–15% of adults aged ≥40 years.1 Over 80% of these patients have mild to moderately severe COPD (forced expiratory volume in 1 s (FEV1) >50% predicted) and, in these patients, the leading cause of mortality is cancer which accounts for >50% of all deaths.2 Previous studies have shown that, while smoking is a shared risk factor for both COPD and lung carcinoma,3 reduced lung function, independent of smoking, is another important risk factor for this type of cancer.4–8 However, several important questions remain unanswered. First, previous studies in this area have focused primarily on the incidence of lung cancer rather than on lung cancer mortality per se. Since early stage lung cancers are potentially curable and since patients with COPD may have more radiographic investigations, ascertainment bias may have confounded the previous studies that have used lung cancer incidence rather than mortality as the primary outcome. Second, although it is known that extrapulmonary cancers account for approximately 20% of all deaths in stage 1 and stage 2 COPD,9 the exact relationship between COPD (and its severity) and these cancers is not well known. Third, and most important from a clinical perspective, it is not known whether the risk of COPD and cancer mortality can be modulated by pharmacological treatment. Several studies suggest that statins (HMG-CoA reductase inhibitors) may reduce the risk of cancer including those in the lungs, pancreas, prostate and colon.10–15 On the other hand, some have suggested that statins may promote the development of new malignancies.16 However, none of these studies has evaluated the effects of statins on cancer mortality in patients with COPD. In the present study we sought to determine (1) the relationship between COPD (and its severity) and the risk of total cancer mortality and (2) whether the use of statins modified this relationship.

METHODS

Study population

The patient population for this study has been described previously.17 We used a cohort of 3371 patients who underwent elective non-cardiac vascular surgery (abdominal aortic surgery, carotid endarterectomy or lower limb arterial reconstruction) between 1990 and 2006. COPD was defined according to the guidelines of the Global Initiative for Chronic Obstructive Lung Disease (GOLD).18 The COPD diagnosis was based on a post-bronchodilator FEV1 to vital capacity ratio of 70% or less on spirometry (which was the case in 82% of the patients with COPD). Patients without spirometry were classified based on the presence of pulmonary symptoms (dyspnoea, sputum production or cough) and use of COPD medications based on the GOLD Guidelines for Management of stable COPD patients.19 Mild COPD was defined as those who had symptoms and were using a short-acting bronchodilator when needed. Moderate COPD was defined as those with symptoms who required regular use of one or more bronchodilators. Severe COPD was defined as those with symptoms who were on regular treatment with one or more bronchodilators plus inhaled corticosteroids (for repeated exacerbations or persistent symptoms) or those patients who required domiciliary long-term oxygen therapy.

Follow-up and end points

At the time of follow-up the municipal civil status of all patients, which was completed in 96%

963
of the patients during a median follow-up of 5 years (inter-
quartile range (IQR) 2.0–9.1). The cause of death was
certained by reviewing medical records, autopsy reports,
contacting the referring physician, general practitioner or
Statistics Netherlands. The primary end point of the study
was total cancer mortality.

Statistical analysis
Cancer mortality rates among the COPD severity groups were
compared using a χ² test. Cumulative long-term survival was
determined by the Kaplan-Meier method and compared using a
log-rank test. Univariate and multivariate Cox regression
analyses were used to determine the association between
COPD (severity) and cancer mortality. In these analyses,
patients without COPD were used as the reference group.
Cox regression analysis was also used to determine the
relationship between statins and cancer mortality. In the
multivariate analysis we adjusted for age, gender, type of
surgery, diabetes, smoking status, hypercholesterolaemia, cortic-
sterooids, aspirin, statins and propensity score (for the
association between statins and cancer mortality). The propor-
tional hazards assumption was verified by visual inspection of
the log-log survival curves and by using the Schoefeld residuals.
This propensity score was developed using a multivariate
logistic regression model to adjust for the likelihood of receiving
a new category of patients with a restrictive disorder (defined as
FEV₁/FVC ratio >80% with FEV₁ <80% of predicted) and
repeated the analysis. Patients with a “restrictive” defect had an
increased risk of total cancer mortality as well as lung and
extrapulmonary cancer mortality (see table 3 in online supple-
ment).

RESULTs
Characteristics of study cohort
The baseline characteristics of the cohort are presented in
table 1. The mean (SD) age was 66 (12) years and 75% were
men. There were 1310 patients (39%) with COPD; mild COPD
(n = 578; 17%), moderate COPD (n = 579; 17%) and severe
COPD (n = 153; 5%). Of the current smokers, 26% used statins
whereas 23% of the never/ex-smokers were statin users
(p = 0.20).

COPD and cancer mortality
Over the follow-up period, 316 patients (9%) died from cancer.
Patients with COPD had an increased risk of cancer mortality
which was dependent on the severity of COPD. The risk of
cancer mortality in patients with no COPD, mild, moderate and
severe COPD was 8%, 10%, 14% and 12%, respectively
(p<0.001). Overall, 102 patients (3%) died from lung cancer.
The risk of lung cancer mortality in patients with no, mild,
moderate and severe COPD was 2%, 3%, 5% and 6%, respectively
(p<0.001).

The cancer-free survival curves stratified by COPD severity
are shown in fig 1 (p<0.001, log-rank test) (see fig 1 in online
supplement for lung cancer-free survival curves). COPD was
independently associated with total cancer mortality (HR 1.61;
95% CI 1.25 to 2.06) (table 2).

We tested the robustness of our findings by repeating the
analysis following the exclusion of COPD patients without
spirometry (see tables 1 and 2 in online supplement). It was
reassuring that these data were very similar to those from the
main analyses. In addition, in a secondary analysis we created a
new category of patients with a restrictive disorder (defined as

during the follow-up period compared with 11% of the patients who did not use statins (p < 0.001); 2% of the patients who used statins died from lung cancer compared with 3% of those who did not use statins (p < 0.05). After excluding patients with lung cancer, extrapulmonary cancer was the cause of death in 4% of those who used statins and 7% of those who did not (p < 0.01). After adjustments for potential confounding factors, statins were not significantly associated with total cancer mortality (HR 0.82; 95% CI 0.57 to 1.20), lung cancer mortality (HR 1.00; 95% CI 0.52 to 1.92) or extrapulmonary mortality (HR 0.74; 95% CI 0.47 to 1.17) (table 3).

**Statins and cancer mortality in patients with COPD**

Of the 1310 patients with COPD, 350 (25%) used statins at baseline. More patients who did not use statins died from cancer than those who used statins (14% vs 6%; p < 0.001). Similar differences were noted when only lung cancer mortality (5% vs 2%; p < 0.01) or extrapulmonary cancer mortality (9% vs 4%; p < 0.01) was considered. Figure 2 presents the long-term cancer-free survival curves of patients with COPD who did and did not use statins (see fig 2 in online supplement for lung cancer-free survival curves). Of the patients who used a statin, 87% survived during the follow-up period compared with 72% of those who did not use statins at baseline (p < 0.01, log rank test). After adjustments, the relationship was attenuated with borderline significance between statins and total cancer mortality (HR 0.57; 95% CI 0.32 to 1.01) and no significance between statins and lung cancer mortality (HR 0.75; 95% CI 0.28 to 2.05) (table 3). However, in this subanalysis including only patients with COPD, statins were associated with reduced cancer mortality from sites other than the lungs (HR 0.49; 95% CI 0.24 to 0.99).

**DISCUSSION**

This large study of patients with peripheral arterial disease demonstrates a significant relationship between COPD and cancer mortality. The risk rises sharply in patients with moderate to severe airflow obstruction (FEV₁ < 80% predicted). Interestingly, both lung and extrapulmonary cancer deaths increased in patients with moderate COPD while, in those with severe COPD, lung cancer mortality predominated.

Our results confirm the findings of previous studies which investigated the association between COPD and lung cancer mortality. A severity-dependent association was found between the FEV₁ quintiles and the risk for lung cancer mortality. Similar relationship was observed in our study; however, for the assessment of COPD severity we used the classifications as defined by the GOLD guidelines instead of FEV₁ quintiles. We found in particular that moderate and severe COPD were independent risk factors for lung cancer mortality. These findings are also in line with the results of three other studies which also investigated the relationship between the GOLD classifications of COPD severity and lung cancer. However, our results could not be compared directly with these studies as they examined the association with lung cancer incidence rather than lung cancer mortality. Although the relationship between COPD and lung cancer is well known, the association of COPD with extrapulmonary cancers is less well established. A study by Purdue et al of construction workers failed to demonstrate a significant association between COPD and the risk of non-pulmonary carcinomas. However, the study was limited by the small number of cancer events (5.7%) and the overwhelming predominance of men (96% of the cohort). By evaluating a group of high-risk patients (ie, older, smoking history, co-morbidities, mix of men and women), our study had sufficient power to demonstrate an independent association of COPD with extrapulmonary cancer mortality. On average, COPD increased extrapulmonary cancer mortality by more than 40%. Our study also suggests that extrapulmonary cancers are particularly important causes of death in patients with moderate (but not mild or severe) COPD.

These data are consistent with previous reports by the Lung Health Study (LHS) and TORCH (Towards a Revolution in COPD Health) groups. The LHS evaluated patients with mild to moderate COPD (average FEV₁ 75% of predicted) whereas the TORCH trial studied patients with more severe diseases (FEV₁ 44% of predicted). In the LHS 21% of deaths were from extrapulmonary cancers while, in the TORCH trial, extrapulmonary cancers only accounted for 7% of the total deaths. Thus, in severe COPD, other competing causes of mortality such as lung cancer and respiratory failure may be important.

The mechanism by which COPD increases cancer risk is largely unknown. Cigarette smoking is a shared risk factor for...
both COPD and solid organ cancers including lung, breast and colorectal cancer. However, in our analysis we adjusted for smoking and still found a significant relationship between COPD and cancer. Moreover, a recent study of lifelong never smokers found a significant relationship between COPD and lung cancer mortality. Collectively, these data suggest that, in addition to cigarette smoking, other potential explanations should be considered. These include (1) shared genetic susceptibility, (2) delayed clearance of inhaled carcinogens because of airflow limitation, and (3) chronic low-grade lung and systemic inflammation associated with COPD. We have found previously that, in patients with COPD, systemic levels of C-reactive protein, a biomarker of systemic inflammation, is associated with a future risk of cancer mortality including those related to extrapulmonary cancers. Similarly, in the largest meta-analysis of its kind, Danesh and colleagues showed that plasma fibrinogen, another non-specific marker of systemic inflammation, is associated with a future risk of cancer mortality including those related to extrapulmonary cancers.

Statins are lipid-lowering drugs that also possess significant anti-inflammatory properties which may have beneficial effects not only on cardiovascular disease but on other co-morbidities associated with COPD. The findings from the present study suggest that, in patients with COPD, statins may be effective in reducing deaths, especially from extrapulmonary cancers. The results of our study are consistent with previous epidemiological studies which have suggested that statins may lower cancer risk. A study by Blais and colleagues found that patients using statins were less likely to be diagnosed with cancer than those using bile acid-binding resins, which indicates that the protective effect of statins is unlikely to be due to their lipid-lowering effect but is probably the result of other effects. The increased risk of cancer conferred by COPD might explain the increased benefit of statins observed in patients with COPD compared with patients with normal pulmonary function. Randomised controlled trials are needed to confirm our findings.

*Adjusted for age, gender, type of surgery, diabetes, smoking, hypercholesterolaemia, corticosteroids, aspirin and propensity score.

There are several limitations to this study. First, as the data were collected retrospectively, residual confounding by measured and unmeasured variables is possible. The results of this study should thus be interpreted cautiously and conservatively. Second, the study population consisted of patients who underwent vascular surgery. Since such patients are more likely to be smokers and to have additional risk factors for cancer than those of the general population, the findings of the present study may not be generalisable to the total population. Third, we did not have complete data on the primary site of the extrapulmonary cancer deaths. Of the 214 patients who died from extrapulmonary cancers, we were able to specify the site in 124 (58%) patients (see fig 1 in online supplement for details). The impact of statins on different types and sources of extrapulmonary cancers therefore remains unknown. Fourth, statin use was categorised based on whether or not patients were treated with statins at the start of the follow-up period. We did not consider change in statin status during the follow-up period. This may have caused classification of statin status, which would have diluted the relationship. Our estimate of the potential effect of statins on cancer mortality is therefore likely to be conservative.

In conclusion, COPD was associated with increased lung and extrapulmonary cancer mortality in this large cohort of patients with peripheral arterial disease undergoing vascular surgery. The risk of lung cancer mortality increased with severity of COPD, whereas the risk of extrapulmonary cancer was significant only in patients with moderate COPD, possibly because of competing risks for mortality in patients with severe COPD. Statins may modulate the risk of extrapulmonary cancer mortality in patients with COPD.

Conclusions: COPD was associated with increased lung and extrapulmonary cancer mortality in this large cohort of patients with peripheral arterial disease undergoing vascular surgery. The risk of lung cancer mortality increased with severity of COPD, whereas the risk of extrapulmonary cancer was significant only in patients with moderate COPD, possibly because of competing risks for mortality in patients with severe COPD. Statins may modulate the risk of extrapulmonary cancer mortality in patients with COPD.
