British Thoracic Society guideline for advanced diagnostic and therapeutic flexible bronchoscopy in adults

I A Du Rand, 1 P V Barber,2 J Goldring,3 R A Lewis,4 S Mandal,5 M Munavar,6 R C Rintoul,7 P L Shah,8 S Singh,9 M G Slade,7 A Woolley,4 on behalf of the British Thoracic Society Interventional Bronchoscopy Guideline Group

SUMMARY OF RECOMMENDATIONS

Diagnosis of mediastinal/hilar lymph nodes and peribronchial masses

Conventional transbronchial fine needle aspiration (TBNA)

B ▶ Conventional transbronchial needle aspiration (TBNA) is a safe technique and should be used to sample mediastinal and hilar lymphadenopathy during initial diagnostic bronchoscopy where a pre-procedure CT scan has demonstrated significant adenopathy.
▶ Conventional TBNA is a safe technique for sampling hilar and mediastinal lymph nodes in cases of suspected sarcoidosis and may be used in conjunction with endobronchial and transbronchial biopsies.
✓ ▶ Depending upon the clinical setting, a non-diagnostic conventional TBNA result may warrant further investigation. Real-time endobronchial ultrasound-guided TBNA (EBUS-TBNA) or surgical lymph node sampling should be considered.

Endobronchial ultrasound-guided transbronchial fine needle aspiration (EBUS-TBNA)

B ▶ EBUS-TBNA is a safe and effective technique for the assessment of hilar and mediastinal lymph nodes in cases of confirmed or suspected lung cancer.
▶ EBUS-TBNA is a safe and effective technique for sampling hilar and mediastinal lymph nodes in cases of suspected sarcoidosis and may be used in conjunction with endobronchial and transbronchial biopsies.
D ▶ EBUS-TBNA is a safe and effective technique for sampling paratracheal and peribronchial intraparenchymal lung masses.
✓ ▶ At present there is insufficient evidence to recommend EBUS-TBNA for routine use in the diagnosis of lymphoma.
✓ ▶ In cases where EBUS-TBNA results are negative for malignancy, a confirmatory surgical biopsy should be performed where appropriate.

Therapeutic procedures for malignant disease

Malignant airway obstruction

1. Endobronchial debulking of tumours
D ▶ In patients with central airway obstruction (CAO) due to intraluminal tumour, endobronchial tumour debulking should be considered.
✓ ▶ When undertaking endobronchial debulking of tumours, a laryngeal mask or uncuffed endotracheal tube is recommended to achieve airway control.

2. Endobronchial electrocautery or diathermy
D ▶ Endobronchial electrocautery may be considered for use with curative intent in benign disease of the airway including incising web-like stenosis, benign tumours and granulation tissue. It may also be considered for primary treatment of early stage non-invasive lung cancer.
✓ ▶ Endobronchial electrocautery may be considered for palliation of malignant CAO, with or without critical airway narrowing.
✓ ▶ When undertaking snare resection, intermittent bursts of electrocautery of not more than 2 s duration should be used while carefully closing the snare until resistance is felt.
✓ ▶ Avoid an FIO2 of >0.4 when undertaking electrocautery to reduce the risk of airway fire.

3. Argon plasma coagulation (APC)
D ▶ APC may be considered for the debulking of obstructing endobronchial tumour.
▶ APC may be considered for tumour debulking in patients without acute critical airway narrowing.
▶ APC may be considered for the treatment of haemoptysis in patients with endobronchial abnormalities.

4. Thermal laser
D ▶ In patients with CAO due to intraluminal tumour, relief of obstruction using Nd-YAG laser may be considered.
✓ ▶ The power setting should be limited to 40 W

5. Cryotherapy and cryoextraction
B ▶ Cryobiopsy may be considered for diagnostic endobronchial tissue sampling to provide large-volume specimens without crush artefact.
D ▶ Cryotherapy may be considered for tumour debulking in patients without critical airway narrowing.
▶ Cryoextraction/cryoextraction may be considered for tumour debulking.

6. Photodynamic therapy (PDT)
D ▶ PDT may be considered for tumour debulking in patients without critical airway narrowing.
✓ ▶ The technique should be available for carefully selected patients on a regional basis.

7. Brachytherapy
C ▶ Brachytherapy should not be used first-line in preference to external beam radiotherapy for the palliation of lung cancer.
D ▶ Brachytherapy should be considered for the palliation of haemoptysis or CAO in locally advanced central lung cancer.

Airway support with stents
D ▶ The use of self-expanding metallic stents may be considered for the treatment of malignant CAO due to extrinsic disease.
▶ Self-expanding metallic stents may be used to maintain airway patency following endobronchial debulking techniques.
▶ Self-expanding metallic stents can be used to restore or maintain airway patency in conjunction with other treatments such as external beam radiotherapy.
INTRODUCTION
Clinical context and need for a guideline
Interventional bronchoscopy has rapidly evolved in recent years. The field includes the use of more complex diagnostic procedures such as endobronchial ultrasound, the use of bronchoscopic interventions for the relief of central airway obstruction (CAO) due to malignancy and, more recently, the development of therapeutic interventions for non-malignant disease. Many practitioners may feel that this is a highly specialist field and that the techniques are experimental, only for tertiary centres. Perhaps they feel that they do not have the expertise to undertake these procedures. The fact is that some of these techniques such as transbronchial needle aspiration (TBNA) really should be part of every bronchoscopist’s practice. Others such as endobronchial ultrasound (EBUS) are rapidly becoming standard practice and should be available to all patients, and some such as bronchial thermoplasty and airway valves are yet to establish their role in routine practice. There are also a large variety of methods of tumour debulking, and it is clearly not easy for a practitioner outside the field to know what are the indications, contraindications, potential benefits and complications of each technique, or which technique to consider learning. This guideline therefore aims to help all those who undertake flexible bronchoscopy to understand more about this important and rapidly developing area.

In August 2007 the Standards of Care Committee of the British Thoracic Society (BTS) invited the Interventional Pulmonology Specialist Advisory Group of the BTS to produce an evidence-based update of the guideline on bronchoscopy and agreed this should now include interventional bronchoscopy. The Working Party decided to start with this new guideline on interventional bronchoscopy.

Target audience of the guideline
This guideline is aimed primarily at practitioners within the UK but may be of relevance to other healthcare systems. It is intended to inform those who undertake or intend to undertake the procedures within the guideline, and also to inform others as to what may be available for patients under their care and the indications, likely response and complications of such procedures. Not all of the procedures may be available in all areas, including some tumour debulking procedures, but at least one of the tumour debulking modalities should be available in each cancer network.

Scope of the guideline
This guideline was formulated following consultation with stakeholders from the medical and nursing professions, patient groups and healthcare management. Advanced diagnostic and therapeutic procedures in adults using a flexible bronchoscope are included in the guideline.

Topics covered in the guideline
- Transbronchial needle aspiration (TBNA) and endobronchial ultrasound-guided (EBUS) TBNA
- Electrocautery/diathermy
- Argon plasma coagulation (APC)
- Laser
- Cryotherapy
- Cryoextraction
- Photodynamic therapy (PDT)
- Brachytherapy
- Tracheobronchial stents
- Electromagnetic navigation bronchoscopy (ENB)
- Endobronchial valves for emphysema
- Bronchial thermoplasty for asthma

Topics not covered in the guideline
- Rigid bronchoscopy
- Auto fluorescence bronchoscopy

Rigid or flexible bronchoscopy for interventional procedures?
This guideline covers interventional procedures performed using flexible bronchoscopy. In many units, however, rigid bronchoscopy alone would be used for such procedures. Most UK respiratory physicians lack training in rigid bronchoscopy, and most
bronchoscopy units outside thoracic surgery centres do not have ready access to rigid bronchoscopy as a back-up for, or as an alternative to, flexible bronchoscopy.

The main advantages of flexible bronchoscopy are:
1. It is widely available.
2. The majority of respiratory physicians are trained to use flexible bronchoscopy.
3. It does not require a general anaesthetic.
4. It provides access to more distant airways and good access to the upper lobe bronchi.

The main advantages of rigid bronchoscopy are:
1. A general anaesthetic is more comfortable for the patient.
2. It allows control of ventilation and oxygenation during interventional procedures.
3. It permits the removal of large volumes of tumour.
4. It provides more control in cases of massive haemoptysis.
5. It permits silicon stent insertion.
6. Obstructing airway lesions can be cored out.
7. Large centrally-placed foreign bodies can be removed.

Most interventional procedures, however, can be undertaken via flexible or rigid bronchoscopy, including removal of many foreign bodies, metallic stent insertion and tumour debulking with diathermy, argon plasma, cryoextraction and photodynamic therapy (PDT). Although thermal lasers can be used with either scope, most practitioners of this technique prefer to use rigid bronchoscopy. Silicone and Y-stents are inserted via rigid bronchoscopy.

METHODOLOGY

This guideline is based on the best available evidence. The methodology used to write the guideline adheres strictly to the criteria as set by the AGREE collaboration in the document, which is available online http://www.agreecollaboration.org/1/agreeguide/

Clinical questions and literature search

Clinical questions were gathered in the PICOT (Patient, Intervention, Control, Outcome and Time) format to define the scope of the guideline and inform the literature search.

Systematic electronic database searches were conducted in order to identify potentially relevant studies for inclusion in the guideline. For each topic area the following databases were searched: Ovid MEDLINE (from 1988) (including MEDLINE In Process), Ovid EMBASE (from 1988), Ovid CINAHL (from 1982) and the Cochrane Library (from 1992) (including the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effects, the Cochrane Central Register of Controlled Trials, the Health Technology Assessment database and the NHS Economic Evaluation Database).

The searches were first run in January 2008 and updated in September 2010. Searches were saved and run on a monthly basis to identify newly published literature to date. Searches included a combination of indexed terms and free text terms and were limited to English language publications only. The initial search identified 3751 potential papers.

Appraisal of the literature

Appraisal was performed using the criteria stipulated by the AGREE collaboration. Each paper was appraised by a pair of reviewers. One individual (IDR) read the title and abstract of each article retrieved by the literature searches and decided whether the paper was definitely relevant, possibly relevant or not relevant to the project. Criteria formulated for categorising the abstracts into these three groups were:

- Whether the study addressed the clinical question.
- Whether the appropriate study type was used to produce the best evidence to answer the clinical question.
- Abstract was in English.
- Studies where exclusively rigid bronchoscopy was used were not evaluated.
- Abstracts were not rejected on the basis of the journal of publication, country in which the research was performed or published nor the date of publication.

The full paper was obtained for all relevant or possibly relevant abstracts and allocated to the relevant section(s) which were broadly grouped as argon plasma, brachytherapy, cryotherapy, diathermy, EBUS, TBNA, endobronchial valves, general interventional bronchoscopy, laser, photodynamic therapy, stents, thermoplasty and virtual bronchoscopy with electromagnetic navigation.

The first screening process identified 1042 of the initial 3751 reference abstracts to be definitely or possibly relevant to the guideline. Two guideline reviewers independently reviewed the abstracts to identify papers to be appraised for the guideline. Three hundred and eighty-seven papers were critically appraised. The two leads for each section independently appraised each paper assigned to them using the Scottish Intercollegiate Guidelines Network (SIGN) critical appraisal checklists. A web-based guideline development tool (http://www.bronchoscopy-guideline.org) enabled each pair of reviewers to collaborate online. The reliability of the evidence in each individual study was graded using the SIGN critical appraisal checklists. The body of evidence for each recommendation was summarised into evidence statements and graded using the SIGN grading system (see table 1). Disagreements were resolved by discussion with the section partner.

Considered judgement and grading of evidence

The Guideline Group used the online-derived evidence tables to judge the body of evidence and grade recommendations for this guideline. Evidence tables are shown in online Appendix 4 available online. Where evidence was lacking to answer the formulated clinical questions, expert opinions were obtained for formal consensus statements using the Delphi method. The following were considered in grading of the recommendations:

- The available volume of the body evidence.
- How applicable the obtained evidence was in making recommendations for the defined target audience of this guideline.

RCT, randomised controlled trial.
A randomised controlled trial (RCT) comparing symptom relief and survival in patients with malignant CAO receiving airway intervention in combination with conventional anticancer therapy versus conventional anticancer therapy alone.

- An RCT comparing EBUS with surgical staging of the mediastinum in lung cancer.
- An RCT comparing EBUS-TBNA with standard bronchoscopic techniques for the diagnosis of sarcoidosis.
- An RCT comparing outcomes including quality of life of treatment by debulking for CAO followed by conventional anticancer treatment with anticancer treatment alone.
- Defining the population or phenotype of disease that benefits from the bronchoscopic lung volume reduction techniques available.
- Further RCTs on the techniques available for bronchoscopic lung volume reduction with improved patient selection.
- Longer-term evaluation of safety and efficacy of bronchial thermoplasty.

Recommended standards of care based on the recommendations in this guideline can be found on the BTS website at: http://www.brit-thoracic.org.uk/.

Drafting of the guideline

The Guideline Committee corresponded regularly by email and meetings of the full group were held in December 2007, June 2008, December 2008, March 2009, June 2009 and October 2009. The guideline was discussed at an open session at the BTS Winter Conference in December 2009. A revised draft guideline document was circulated to all the relevant stakeholders for consultation in May 2010 followed by a period of online consultation. The BTS Standards of Care Committee reviewed the draft guideline in July 2010. Further revision was made in September 2010 following the incorporation of suggestions by international experts in interventional bronchoscopy. The guideline was reviewed by the BTS Standards of Care Committee in November 2010 and submitted for publication.

The Guideline Group members adhered to the BTS policy for the Declaration of Interests and, where appropriate, specific interests are declared in Appendix 1.

The guideline will be reviewed and updated in 2015.

Audit, research and training recommendations

Audit

- All those undertaking any interventional procedure are advised to maintain records of each procedure including indication, outcome and complications for audit purposes.
- It is recommended that a database should be kept of all those in the UK undertaking interventional procedures and numbers being treated.
- The database should include details of current training in interventional procedures available in the UK.

Research

- A randomised controlled trial (RCT) comparing symptom relief and survival in patients with malignant CAO receiving interventional bronchial diathermy. To be competent in any specialised technique it is useful to have attended a course and undertaken the procedure on a model, but it is also necessary to have received experience in a centre undertaking the procedure and also to have hands-on experience. Evidence on training requirements is sparse.

There are published recommendations for training by the American College of Chest Physicians and also in the ERS/ATS statement on interventional pulmonology. The Guideline Group has decided not to quote specific numbers of procedures required to be performed before an individual is deemed competent as these numbers are usually arbitrary. Individuals have different learning curves and hence focus should be towards monitoring an individual’s performance and outcomes. Standards for particular procedures need to be determined and agreed. These can then be used for outcome-based assessment of competency.

RCT, randomised controlled trial.
position is determined from study of a pre-procedure CT. Virtual bronchoscopy using CT reconstructions has recently been described and can be used to help identify suitable positions for TBNA. Lymph nodes stations that can be accessed in this way are 2R, 2L, 3P, 4R, 4L, 7, 10R, 10L, 11R and 11L (figure 1).

Ultrasound guidance may be used to locate lymph nodes for TBNA. In early descriptions a radial ultrasound miniprobe introduced through the working channel of a conventional bronchoscope was used to locate lymph nodes. The miniprobe was then removed and a TBNA needle was introduced to puncture the node at the predetermined position. This technique did not allow for real-time ultrasound visualisation of the TBNA. More recently, real-time EBUS-TBNA has been described which involves use of a convex array linear ultrasound bronchoscope. The use of real-time ultrasound imaging during TBNA allows specific nodes to be targeted and permits accurate biopsy of multiple lymph node stations when necessary for staging. Lymph nodes as small as 4 mm in the short axis have been sampled.

The technique of TBNA is simple. Diagnostic yield is dependent upon operator experience, the position and the size of the lymph node. The use of rapid on-site cytopathology improves yield. A guide on how to perform TBNA is available in Appendix 2.

Indications

TBNA is mainly used to sample hilar and mediastinal lymph nodes. It can also be used to sample paratracheal and peribronchial lung masses.

Complications

Conventional (non-ultrasound-guided) TBNA is safe with few reported complications. In a meta-analysis by Holt et al the pooled complication rate was 0.3%.

Ultrasound guidance may be used to locate lymph nodes for TBNA. In early descriptions a radial ultrasound miniprobe introduced through the working channel of a conventional bronchoscope was used to locate lymph nodes. The miniprobe was then removed and a TBNA needle was introduced to puncture the node at the predetermined position. This technique did not allow for real-time ultrasound visualisation of the TBNA. More recently, real-time EBUS-TBNA has been described which involves use of a convex array linear ultrasound bronchoscope. The use of real-time ultrasound imaging during TBNA allows specific nodes to be targeted and permits accurate biopsy of multiple lymph node stations when necessary for staging. Lymph nodes as small as 4 mm in the short axis have been sampled.

The technique of TBNA is simple. Diagnostic yield is dependent upon operator experience, the position and the size of the lymph node. The use of rapid on-site cytopathology improves yield. A guide on how to perform TBNA is available in Appendix 2.

Evidence

The majority of papers on conventional TBNA are case series. One meta-analysis by Holt et al has been reported. The reported sensitivities for this approach vary considerably. In their analysis Holt et al divided studies according to whether or not they had surgically confirmed all TBNA results and enrolled at least 10 patients with and without mediastinal metastasis. In six studies that met these entry criteria, pooled sensitivity and specificity for diagnosis of malignancy were 39% (95% CI 17% to 61%) and 99% (95% CI 96% to 100%), respectively. However, the prevalence of mediastinal metastases in these studies was only 54%. Analysis of another group of studies in the review by Holt et al in which the prevalence of mediastinal metastases was 81% had a pooled sensitivity for the detection of malignancy of 78% (95% CI 71% to 84%). A similar figure was reported by Deterbeck et al. In their review of the literature they reported a pooled TBNA sensitivity of 78% and specificity of 99%. The prevalence of disease in this pooled analysis was 75%.

Two studies have demonstrated that 5–7 aspirates per node are required before a plateau in diagnostic accuracy is achieved. The success rate is highest in lymph nodes >20 mm in the short axis and in the station 4R and 7 lymph node locations (figure 1).

Rapid on-site cytology may improve the success rate and reduce the number of needle aspirates and the number of lymph node stations sampled.

The role of TBNA in the diagnosis of sarcoidosis has been reported. Considering TBNA alone, the diagnostic yield in stage I disease (61–82%) was higher than in stage II (42–75%). However, most operators use TBNA in this setting in conjunction with endobronchial and transbronchial biopsies and diagnostic yields of around 90% are achievable in stage I and II disease.

Evidence statement

Conventional TBNA is a safe technique to sample mediastinal and hilar lymphadenopathy at initial diagnostic bronchoscopy in cases of either suspected malignant involvement or sarcoidosis. (Evidence level 2++)

Recommendations

Conventional TBNA is a safe technique and should be used to sample mediastinal and hilar lymphadenopathy at initial diagnostic bronchoscopy where a pre-procedure CT scan has demonstrated adenopathy. (Grade B)

Conventional TBNA is a safe technique for sampling hilar and mediastinal lymph nodes in cases of suspected sarcoidosis and may be used in conjunction with endobronchial and transbronchial biopsies. (Grade B)

Good practice points

Depending upon the clinical setting, a non-diagnostic conventional TBNA result may warrant further investigation. Real-time EBUS-TBNA or surgical lymph node sampling should be considered. (✓)
Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA)

EBUS-TBNA provides images of the mediastinal structures immediately surrounding the tracheobronchial tree.

Indications

EBUS-TBNA is mainly used to sample hilar and mediastinal lymph nodes. It can also be used to sample paratracheal and peribronchial lung masses.

Complications

In most centres the procedure is performed under moderate sedation. No advantage has been demonstrated by performing the technique under general anaesthesia. The reported safety profile is excellent. In their meta-analysis, Gu et al reported only two complications in 1299 patients (0.15%).

Evidence

In 2009, two meta-analyses and one systematic review reported the sensitivity and specificity of EBUS-TBNA. Adams et al and Gu et al reported that the pooled sensitivity for EBUS-TBNA was 88% (95% CI 70% to 94%) and 0.95 (95% CI 91 to 94%), respectively. In their systematic review Varela-Lema et al reported that sensitivity for the diagnosis of malignancy ranged from 85% to 100%. In all three reports the specificity was 100%, but this figure is artificial as positive TBNA results were not confirmed by surgical resection. It should be noted, however, that many of the published case series upon which the systematic reviews are based come from a relatively small group of investigators and further experience is needed to see if these results can be widely replicated.

Although in case series the reported sensitivity for the detection of malignancy in mediastinal lymph nodes is similar to that of mediastinoscopy, there are no reported prospective studies comparing the accuracy of EBUS-TBNA and mediastinoscopy for staging of lung cancer.

Tournoy et al reported on the sensitivity of EBUS-TBNA for diagnosis of malignancy from intraparenchymal lung masses. In this study of 60 patients they reported a sensitivity of 82% (95% CI 69% to 91%). A similar study by Nakajima et al reported a sensitivity of 94% in 35 patients.

One US-based study has reported the use of EBUS-TBNA in the diagnosis of lymphoma. In a retrospective review of 25 patients who underwent EBUS-TBNA for suspected lymphoma, 10 of 11 patients with a final diagnosis of lymphoma were correctly identified, giving a sensitivity of 90.9% and a specificity of 100%. Despite these impressive results, the applicability of EBUS-TBNA for the diagnosis of lymphoma in the UK is unclear, given that histopathology is often required for the final diagnosis.

Four studies have assessed the clinical usefulness of EBUS-TBNA in the diagnosis of sarcoidosis. In these case series EBUS-TBNA was diagnostic in 88–93% of patients. However, it should be noted that the pre-test probability of a final diagnosis of sarcoidosis in these series was high. At present there is no evidence to indicate that EBUS-TBNA sampling of lymph nodes is any more or less effective for identifying non-caseating granulomas than transbronchial/endobronchial lung biopsies combined with bronchoalveolar lavage. A clinical trial addressing this issue is currently underway.

EBUS-guided TBNA has high sensitivity and specificity for identifying malignancy in mediastinal and hilar lymph nodes in patients with lung cancer. (Evidence level 2++)

EBUS-TBNA has high sensitivity for identifying malignancy when used for sampling paratracheal and peribronchial parenchymal lung masses. (Evidence level 3)

EBUS-TBNA has a high sensitivity for identifying non-caseating granulomas in hilar and mediastinal lymph nodes in cases of suspected sarcoidosis. (Evidence level 2++)

The complication rate of TBNA under EBUS guidance is very low, indicating that it is a safe procedure. (Evidence level: 2++)

Recommendations

EBUS-TBNA is a safe and effective technique for the assessment of hilar and mediastinal lymph nodes in cases of confirmed or suspected lung cancer. (Grade B)

EBUS-TBNA is a safe and effective technique for sampling paratracheal and peribronchial intraparenchymal lung masses. (Grade D)

EBUS-TBNA is a safe and effective technique for sampling hilar and mediastinal lymph nodes in cases of suspected sarcoidosis and may be used in conjunction with endobronchial and transbronchial biopsies. (Grade B)

At present there is insufficient evidence to recommend EBUS-TBNA for routine use in the diagnosis of lymphoma. (Grade D)

Good practice point

In cases where EBUS-TBNA results are negative for malignancy, a confirmatory surgical biopsy should be performed where appropriate.

THERAPEUTIC PROCEDURES FOR MALIGNANT DISEASE:
MALIGNANT AIRWAY OBSTRUCTION

Endobronchial debulking of tumours

Most new diagnoses of lung cancer are made at an advanced disease stage with 50% of patients having involvement of the central airways either due to endobronchial disease, extrinsic compression or both. Endotracheal or endobronchial obstruction by malignant disease may lead to cough, breathlessness and obstructive pneumonia.

Endobronchial therapy may result in improvement of symptoms and quality of life. There are a number of treatment options available for relieving such symptoms including external beam radiotherapy. However, endobronchial debulking of tumours using rigid and flexible bronchoscopy is commonly used in some centres, especially when such techniques are readily available. There is a need to know the frequency of use of the various debulking techniques, and for more studies to compare the response to other forms of symptom palliation including external beam radiotherapy.

Rigid bronchoscopic procedures under general anaesthesia combine the ability to maintain adequate ventilation, to remove large volume tumour and safely control large volume haemorrhage, but the widespread availability of, and increasing experience in, flexible bronchoscopy has led to an increasing use of flexible bronchoscopic procedures for debulking. Available procedures for debulking endobronchial tumours via flexible bronchoscope include:

1. Electrocautery/diathermy
2. Argon plasma coagulation (APC)
3. Thermal laser
4. Cryotherapy
5. Cryoextraction/cryorecanalisation
6. Photodynamic therapy (PDT)
7. Brachytherapy

Some of these procedures offer immediate relief of symptoms and in others the benefit is delayed. Where there is extrinsic compression of the airway, insertion of a stent may be more appropriate. When these procedures are performed, there should be adequate airway control since they carry significant risks of haemorrhage, respiratory failure and cardiac arrhythmias. A secure airway such as an endotracheal tube or laryngeal mask should be considered since this allows rapid and repeated insertion of the bronchoscope, high volume suction and the deployment of a balloon bronchial blocker. An example of a malignant airway obstruction flow diagram is shown in Appendix 3.

**Recommendation**

- In patients with CAO due to intraluminal tumour, endobronchial tumour debulking should be considered. (Grade D)

**Good practice point**

- When undertaking endobronchial debulking of tumours, a laryngeal mask or uncuffed endotracheal tube is recommended to achieve airway control. (J)

**Electrocautery or diathermy**

**Principles**

Electrocautery (also known as diathermy) uses high-frequency electric current to cause heating which leads to coagulation at lower temperatures or tissue vapourisation at higher temperatures. The current is delivered endobronchially via a probe, snare or needle knife. The degree of tissue destruction depends on the power used, the duration and surface area of contact, and the density and moisture content of the tissue. A monopolar technique is used in the airways. The current passes from the applicator device, through the body to a return electrode usually applied to a limb. Low voltage, low power and high current settings will cause coagulation, while high voltage and low current will cause carbonisation (‘cutting’). Most electrocautery devices use a blend of cut and coagulation waveforms.

**Technique**

The equipment required for electrocautery is a high-frequency electrocautery generator and a selection of devices for endobronchial application. These may include a wire snare, probe, needle knife and ‘hot’ or punch biopsy forceps. The passage of an uncuffed endotracheal tube over the flexible bronchoscope at the beginning of the procedure can facilitate repeated removal of resected tissue. The initial energy setting (around 20 W) should be tested on normal mucosa before treating the lesion. Duration of treatment will affect the depth of tissue damage. Van Boxem et al showed that, at a power setting of 30 W, the depth of tissue necrosis increased with duration of application, from 0.1 mm after 1 s progressively to 1.9 mm after 5 s. Longer duration of coagulation (3–5 s) caused damage to underlying cartilage. It is necessary to continuously remove mucus, debris and blood to avoid current leakage.

The probe may be used to vapourise superficial tumours. The snare is useful for debulking large volumes, especially of polypoid tumours. It may be necessary to take a number of separate sections of tumour before the airway is opened up. Removal of large volume tumour from the airway can be achieved in a variety of ways including suction, grasping or biopsy forceps, or use of a cryoprobe. The knife is particularly useful for resecting benign webs.

**Indications**

Electrocautery has been used for treating benign and malignant disease, and with both curative and palliative intent. The prospective management of benign stenoses using electrocautery is effective. It has also been used for removal of granulation tissue and removal with curative intent of both benign and early stage malignant tumours with a visible distal margin and <5 mm invasion of the bronchial mucosa and no invasion of the cartilage. Radiographically occult lung cancer can be treated with bronchoscopic electrocautery. Electrocautery has principally been used for the palliation of malignant CAO. It appears to be as effective in achieving tumour debulking as the neodymium-yttrium-aluminium-garnet (Nd:YAC) laser and can provide immediate relief of symptoms.

**Complications**

The main complication of diathermy is bleeding. In the largest series this occurred in 1.56 cases. Airway fire has been described. To avoid this complication, a fractional inspired oxygen (FIO2) of 0.4 or less is recommended, and some groups recommend switching off supplemental oxygen during diathermy use.

Careful application of the patient plate and the use of insulated bronchoscopes reduce the risk of current leakage causing burns. Use in patients with pacemakers should be avoided if possible but, if use is unavoidable, guidelines for reducing risk are available from the Medicines and Healthcare products Regulatory Agency (MHRA). It is recommended that the skin surface overlying a metallic joint prosthesis be avoided when placing return electrodes for electrocautery.

**Evidence**

The evidence for palliation of airway obstruction from both primary and metastatic lung tumour comes from case series alone. The results are consistent, with successful outcomes in 39/56 patients, and 27/82 patients and 35/37 patients. A safety study undertaken by Horinouchi et al concluded that electrocautery is a safe and reliable procedure when used according to strict guidelines, which include a power output not exceeding 30 W for punch biopsy and snare resection, 20 W for probe, and 10 W for needle knife. To prevent airway fire the authors allowed supplemental oxygen only when electrical current was not being applied.

**Evidence statements**

- Endobronchial electrocautery has an acceptable safety profile in experienced hands provided appropriate device settings are employed. (Evidence level 3)

- Endobronchial electrocautery is effective for endobronchial tumour debulking, with or without critical airway narrowing. (Evidence level 3)

- Endobronchial electrocautery is effective in the treatment of early stage lung cancer. (Evidence level 3)

- Endobronchial electrocautery is effective in the treatment of benign tumours and stenoses of the airways. (Evidence level 3)

**Recommendations**

- Endobronchial electrocautery may be considered for use with curative intent in benign disease of the airway including incising web-like stenosis, benign tumours and granulation tissue. It may also be considered for primary treatment of early stage non-invasive lung cancer. (Grade D)
Endobronchial electrocautery may be considered for palliation of malignant CAO, with or without critical airway narrowing. (Grade D)

Good practice points
- When undertaking snare resection, intermittent bursts of electrocautery of not more than 2 s duration should be used while carefully closing the snare against resistance. (√)
- Avoid an FiO2 of >0.4 when undertaking electrocautery to reduce the risk of airway fire. (√)

Argon plasma coagulation (APC)

Principles
APC is a non-contact mode of electrocautery that can be delivered using flexible bronchoscopy. It causes desiccation and coagulation of exophytic endobronchial tumours, and can provide rapid haemostasis when used to treat haemoptysis arising from visible endobronchial lesions.39-43

Technique
The technique requires a suitable high-frequency current generator, a source of argon, a return electrode and a flexible delivery catheter containing a monopolar treatment electrode. The treatment catheter is made from a Teflon tube, typically of 1.5 mm or 2.3 mm in diameter, which contains a thin wire. The wire conducts the high-frequency current to the tip of the catheter where it ends in a tungsten electrode. The computer-controlled high-frequency generator sends high-voltage high-frequency current to the electrode, while argon is delivered along the catheter at a flow rate of 0.3-2.0 l/min. Argon plasma is produced at the tip and emerges from the catheter as a spray of coagulating current, which seeks the path of least electrical resistance to the return electrode through the patient. It is recommended that the skin surface overlying a metallic joint prosthesis be avoided when placing return electrodes for APC. As the current passes through the bronchial mucosa, resistance within the tissue leads to heating, coagulation and desiccation. Increasing electrical resistance in the coagulated tissue in turn limits current flow and therefore the depth of coagulation, which is about 2 mm after a 2 s application. This self-limiting effect of APC is a useful feature for endobronchial application, reducing the risk of bronchial perforation.

Indications
APC is principally used for:
- The treatment of haemoptysis caused by lesions within the central airways.
- Debunking of exophytic endobronchial tumours, both benign and malignant.
- Debunking of granulation tissue arising as a complication of tracheobronchial stent insertion.

The published studies of APC do not permit the identification of patients most likely, on clinical or radiological grounds, to benefit from the procedure.

Contraindications
In common with other ablation procedures performed using flexible bronchoscopy, APC should not normally be used for the treatment of lesions causing significant tracheal obstruction unless facilities are immediately available for securing the airway in the event of complications. Such lesions can more safely be treated by flexible bronchoscopy under general anaesthesia with endotracheal intubation or by rigid bronchoscopy. As with laser or electrocautery, APC is contraindicated where there is a requirement for a FiO2 of >0.4 because of the theoretical risk of endobronchial fire, although this complication has not been described in the literature. Most modern implantable cardiac pacemakers or defibrillators are compatible with diathermy/ APC, but advice should be sought from the patient’s cardiologist prior to the procedure.

Complications
No procedure-related complications were described in the studies of Morice et al, Crosta et al and Okada et al.39 41 42 One patient died within 48 h of the procedure but this was ascribed to neutropenic sepsis. In the study by Reichele et al, 5/364 patients (1.4%) developed bronchial or tracheal perforations, all of which resolved on treatment.40 Three patients developed temporary post-procedural neurological complications and two patients died (myocardial infarction, hypovolaemic shock). The neurological and cardiac complications in these five patients may have been caused by intracardiac gas embolism. This has also been described by Reddy et al44 who reported three cases of intracardiac gas embolism (two fatal) occurring after APC over a period of 3 years, an estimated incidence of 1.3-2%. All were treated using rigid bronchoscopy and it is not clear whether gas embolism arose as a complication of APC or of jet ventilation. The overall incidence of significant complications appears therefore to be approximately 2%.

Evidence
The use of APC to treat CAO or haemoptysis using flexible bronchoscopy was examined in four retrospective case series involving 123 patients.39 41-43 In a much larger retrospective analysis of 364 prospectively collected cases,40 rigid bronchoscopy was used in more than 90%, but a flexible bronchoscope was passed through the rigid bronchoscope to deliver the treatment.

The studies used different outcome measures for relief of CAO, retrospectively specified in all except the study by Reichele et al.40 The outcome measure used for haemoptysis was consistent—namely, non-recurrence during follow-up.

In treating CAO, APC consistently improved symptoms and airway patency in all studies. In the only study with predefined outcomes, APC produced complete or partial success in reopening the treated airway in two-thirds of patients (124/186).40 The treatment of haemoptysis was described as being completely successful in 149/150 patients. The evidence is from case series alone but the outcomes are consistent.

Contraindications
- APC is effective in the treatment of CAO. (Evidence level 3)
- APC is effective in the treatment of haemoptysis due to endobronchial disease. (Evidence level 3)
- APC delivered via flexible bronchoscopy for the treatment of CAO or haemoptysis due to endobronchial lesions has a major complication rate of 2%. (Evidence level 5)

Recommendations
- APC may be considered for the debunking of obstructing endobronchial tumour. (Grade D)
- APC may be considered for tumour debunking in patients without acute critical airway narrowing. (Grade D)
- APC may be considered for the treatment of haemoptysis in patients with endobronchial abnormalities. (Grade D)

Thermal laser

Principles
Laser therapy for the relief of endobronchial obstruction was first described in 1974 using the CO2 laser. The majority of
publications report use of the Nd-YAG laser. In laser therapy the heat energy from laser light is used to coagulate and vapourise endobronchial tissue.

**Technique**

The technique can be delivered via rigid or flexible bronchoscopy. Low-power laser is used initially to coagulate tissue to reduce the risk of bleeding. The laser fibre tip should be at least 3 mm from the target tissue to avoid the tissue being vapourised. Continuous suction is used during the procedure to remove smoke from the airways, and continuous inspection of non-obstructed airways is performed to remove any debris and to optimise ventilation. Inspired oxygen is limited to 40% to reduce the risk of airway fire. Laser exposure should be kept to a minimum.

**Indications**

The main indication for laser therapy is the immediate relief of endobronchial obstruction due to primary lung cancer or metastatic disease.

**Complications**

Complications include massive haemorrhage (1%), pneumothorax (0.4%) and pneumomediastinum (0.2%). The peri-procedural death rate is 2–3%. Thermal laser causes more airway scarring and subepithelial fibrosis than other immediate debulking techniques such as diathermy, argon plasma and cryoextraction. With the Nd-YAG laser the literature suggests that the complication rate can be reduced by limiting the power setting to a maximum of 40 W.

**Evidence**

Data are almost entirely from case series and, although outcome data in many of these series are poorly documented, laser therapy appears to be effective in providing rapid relief of endobronchial obstruction with symptomatic improvement in around 70–80%. One-year survival following treatment was around 50%. There is some evidence that outcomes are better if the airway is not totally occluded prior to treatment. Laser therapy has no role in airway occlusion due to extrinsic compression.

Nd-YAG laser is a technique with considerable set-up and maintenance costs. Coulter et al and Boxem et al reported that electrocautery was as effective as laser in the palliation of endobronchial tumour, but is less expensive.

**Evidence statements**

- Nd-YAG laser is effective for endobronchial tumour debulking, with or without critical airway narrowing. (Evidence level 3)
- There is no role for laser therapy in endobronchial obstruction caused by extrinsic compression. (Evidence level 3)

**Recommendation**

- In patients with CAO due to intraluminal tumour, relief of obstruction using Nd-YAG laser may be considered. (Grade D)

**Good practice point**

- Limit power setting to 40 W.

**Cryotherapy and cryoextraction**

**Principles**

Cryotherapy uses extreme cold to cause delayed local destruction of tissue. It is applied in cycles of freezing and thawing, causing tissue necrosis.

**Technique**

Cryotherapy is currently used in two different ways. Standard cryotherapy uses a cryoprobe inserted through the instrument channel of a bronchoscope and applied directly to the target tissue. The tissue is frozen and then allowed to thaw, and repeated freeze-thaw cycles lead to tissue necrosis. One disadvantage of standard cryotherapy is the need to repeat bronchoscopy 3–7 days later to remove necrotic material.

A newer form of cryotherapy, 'cryoextraction', is performed with probes which have an improved join between gas channel and probe in order to withstand much greater forces. The probe is applied to the tissue and the freeze cycle activated for 3–7 s (depending on the tissue composition). The bronchoscope is then removed with the cryoprobe and attached tumour tissue. The tissue is allowed to thaw once it is removed from the airway. This technique is undertaken using an endotracheal airway to facilitate repeated removal and reinserterion of the bronchoscope.

**Indications**

Cryotherapy—and, in particular, cryoextraction—is mainly indicated as a palliative measure in malignant airway obstruction. Cryoextraction can also be effectively applied to remove foreign objects and blood clots from the airways. There may be an indication for the treatment of low-grade malignant lesions such as adenoid cystic carcinoma and early cancer such as carcinoma in situ. The quality of specimens obtained using cryoextraction with absence of crush artefact has led to its use for endobronchial and transbronchial lung biopsy.

**Complications**

Cryotherapy appears to be safe in the treatment of malignant endobronchial obstruction. In case series, the complications observed were haemoptysis (4–10%), bronchospasm (4.5%), cardiac arrhythmia (11%) and death (1.3%).

One case series reported on cryoextraction for recanalisation (cryorecanalisation) with a 10% rate of significant bleeding (six patients) managed with conservative measures and APC; no deaths were reported in the series. Another recent case series reported significant bleeding requiring APC or blocking devices in 8%.

**Evidence**

In the largest case series comprising 521 patients, cryotherapy appeared effective in the treatment of malignant endobronchial obstruction. Technical success as judged by restoration of airway patency was 61% and improvement occurred in symptomatic cases such as haemoptysis (61–76.4%), cough (69%) and dyspnoea (59–81%). One- and two-year survivals were 38.4% and 15.9%, respectively. Another series of 225 patients showed airway patency restoration (complete or partial) in 91%. A lot of the evidence base is from one centre which performed the procedure with a combination of rigid bronchoscopy and a flexible bronchoscope. The reviewers felt it was still important evidence that could be included in this guideline for flexible bronchoscopy, particularly as the technique can just as easily be performed by flexible bronchoscopy.

In one series where 57 patients with malignant tracheal bronchial obstruction were managed by bronchoscopy and cryoextraction, complete recanalisation was observed in 61% and partial restoration of patency in a further 22%. Since cryoextraction produces immediate results (unlike conventional cryotherapy), it may be used for the management of acute tracheal or bronchial obstruction. Eighty-five per
BTS guidelines

cent of patients with endobronchial stenosis could be treated with immediate response. Application of this technique is possible at the lobar or segmental level.

In a recent multicentre trial, cryobiopsy sensitivity was 95% compared with forceps sensitivity of 85%.67 The use of cryobiopsy for transbronchial lung biopsy has also been described. In a trial of 41 patients the mean specimen diameter was 15.11 mm with the cryoprobe compared with 5.82 mm with conventional forceps. Pneumothorax occurred in two patients.67

Evidence statements
► Cryotherapy has an acceptable safety profile in the treatment of malignant endobronchial obstruction. (Evidence level 3)
► Cryotherapy is effective in the treatment of malignant endobronchial obstruction without critical airway narrowing. (Evidence level 3)
► Cryorecanalisation/cryoextraction is effective in the treatment of malignant endobronchial obstruction both with and without critical airway narrowing. (Evidence level 3)

Recommendations
► Cryotherapy may be considered for tumour debulking in patients without critical airway narrowing. (Grade D)
► Cryobiopsy may be considered for diagnostic endobronchial tissue sampling to provide large-volume specimens without crush artefact. (Grade B)
► Cryorecanalisation/cryoextraction may be considered for tumour debulking. (Grade D)

Photodynamic therapy (PDT)
Principles
PDT uses a systemic photosensitiser, most commonly a haematoxylin derivative, selectively retained and concentrated in tumour tissue to render the tumour sensitive to light of a given wavelength. The sensitised tumour is then illuminated by laser light of that wavelength, usually 680 nm at the red end of the spectrum. In the presence of sensitiser and oxygen, laser light illumination causes tumour cell death by a complex pathway triggered by the release of singlet oxygen.

Technique
PDT requires a photosensitiser, a diode laser and a flexible light-guide, at the end of which is either a radial diffuser or a forward-projecting microlens. The photosensitiser most often used has been intravenous porflorin sodium administered in a dose of 200 mg/kg. The laser with its calibration device is a compact desktop instrument. Forty-eight hours after the administration of photosensitiser the tumour is illuminated by laser light using a flexible light-guide passed down the working channel of a standard flexible bronchoscope. The use of PDT lasers requires standard laser safety precautions, principally to address the risk of ocular damage. There are no thermal risks.

Indications
PDT has been used for the treatment of:
► Early central lung cancer, defined as visible endoscopically but not on imaging.
► The palliative treatment of malignancy causing endobronchial large airway obstruction.

Complications
Hematoporphyrin derivatives are taken up by skin, causing sensitivity to sunlight or bright direct light for up to 8 weeks. Protection of exposed areas is necessary, but indoor light is safe and some light exposure is required to photobleach the sensitiser from the skin. In one series of nine patients there was one massive haemoptysis and one bronchopleural fistula.68 Complications may arise from delayed necrosis of treated tissue.

Compared with electrocautery, more airway scarring and more subepithelial fibrosis were seen after treatment with PDT.49

Organisation and cost
PDT requires the purchase or loan of a diode laser. Intravenous PDT sensitisers are expensive. Light-guides are reusable, being deployed inside a disposable plastic sheath.

Evidence
In the treatment of early central lung cancer, complete responses have been reported in 50–100% of patients and at least 80% in most series.69–71 Around a third of patients have required two treatments and a few have needed three treatments. Partial responders can be considered for other treatments including resection or radiotherapy if appropriate. Better responses have been reported for tumours 1 cm or less in diameter. Overall 5-year survival rates have been around 50%, cancer-specific survival up to 90%.

There are only a few series reporting the effect of PDT in palliating the endobronchial symptoms of advanced lung cancer, but it has been shown to be effective for palliation before or after other treatments. Moghissi et al reported experience of 100 cases, 82% of whom had been pretreated.72 Mean endoluminal obstruction (estimated bronchoscopically) fell from 86% to 17.5% with significant increases in forced expiratory volume in 1 s (FEV1). All patients had symptomatic relief and 20% had a complete endoscopic response for 5–19 months. There was no treatment-related mortality in this series.

In a review of 12 papers comprising 656 patients with advanced lung cancer, almost all patients had some relief in cough and dyspnoea.73 Comparisons with YAG laser treatment suggests more prolonged symptomatic relief with PDT,74 but it has also been used in combination with YAG laser and with endobronchial radiotherapy, with some evidence of a better response to combined treatments.

Evidence statements
► PDT is effective in tumour debulking and palliation of symptoms in tracheobronchial obstruction from non-small cell lung carcinoma. (Evidence level 1–)
► PDT is effective in the palliation of advanced tracheobronchial lung cancer, although adverse events including haemoptysis can occur. (Evidence level 2+)
► PDT is effective in the curative treatment of early stage lung cancer. (Evidence level 2+)

Recommendations
► PDT may be considered for tumour debulking in patients without critical airway narrowing. (Grade D)
► PDT can be considered for the curative treatment of early central lung cancer, especially for tumours 1 cm or less in diameter and provided there is no imaging evidence of extrabronchial involvement. (Grade D)
► PDT can be considered for the curative treatment of recurrent lung cancer, for localised endobronchial disease in patients who are not fit for surgery or radical radiotherapy. (Grade D)

Good practice point
► The technique should be available for carefully selected patients on a regional basis, administered by physicians or
surgeons with a particular interest and expertise in lung cancer, bronchoscopy and airway management. (4)

Endobronchial brachytherapy

Principles
The word derives from the Greek ‘Brachis’ meaning ‘close to’. It refers to the placement of radioactive sources within or alongside tumours, enabling an effective local dose to be administered but sparing surrounding tissues from the effects of radiation. The use of brachytherapy for lung tumours has been made possible by the development of high dose rate sources enabling treatment to be administered in minutes rather than hours. The technique is suitable for the relief of large airway obstruction and the relief of haemoptysis and other symptoms caused by endobronchial tumour. It can also be used with curative intent for tumours which are small enough to be encompassed by the limited field of radiation.

Technique
Most centres have used iridium-192, an artificially manufactured isotope. The treatment source consists of a series of iridium pellets housed in a stainless steel capsule approximately the size of a rice grain. It is welded to a drive cable and housed in a safe. A flexible bronchoscope is used to place an applicator (a blind-ending catheter) within or alongside an intraluminal tumour. The bronchoscope is then removed over a long guidewire, leaving the applicator in situ. The guidewire is removed and replaced by a radiodense graduated metal insert. A chest x-ray is taken and the treatment length planned using the insert and its relationship to the main carina to localise the area to be treated. The insert is then removed and the applicator connected to the safe. The radioactive source is then delivered by its drive cable to preplanned positions inside the applicator. The treatment length is determined by the number of positions selected and the diameter of the treatment field is determined by the dwell time at each position. Typically, in a sausage-shaped field, some 10×2 cm is administered. The treatment takes only a few minutes and is therefore suitable for outpatient or day case use. Most centres have used fractionated regimes, typically three fractions of 5–7.5 Gy, but the treatment is also effective as a single fraction of 15 Gy.

Indications
The technique is suitable for the primary and secondary palliation of symptoms caused by large airway obstruction including cough, shortness of breath, haemoptysis and obstructive collapse. It is effective for the treatment of endobronchial tumour and submucosal/peribronchial infiltration. It is not suitable for the treatment of extrinsic compression. It offers flexibility in a number of situations such as bilateral or multiple tumours, or in patients who have been pre-treated with other techniques including external beam radiotherapy. It may be considered for the attempted cure of early central lung cancer subject to accurate local staging to confirm that there has not been extrabronchial spread of tumour.

Complications
Some patients develop radiation bronchitis and occasionally stenosis. The principal serious risk is of massive haemoptysis, often occurring as a late complication in good responders, and more likely to occur with a higher local radiation dosage—that is, in patients who have also received external beam radiation either sequentially or concurrently.

Organisation and cost
The equipment is expensive to purchase but can also be used to treat other organ sites and is usually available in major radiotherapy centres. It requires the availability of flexible bronchoscopy, preferably within the radiotherapy treatment area, and needs good collaboration between physician/endoscopist and clinical oncologist. Health economics comparisons are not straightforward, but it compares favourably with multifraction external beam treatments in terms of cost and patient convenience and avoids the side effects of external beam radiation, especially oesophagitis. It should be available to cancer networks as a treatment option for selected patients.

Evidence
Brachytherapy has been shown to be effective in the palliation of previously untreated inoperable lung cancer, relieving cough in 20–70% of patients, dyspnoea in 25–80% and haemoptysis in 70–90%. The relief of obstructive collapse has been reported in around 25% of patients. Endoscopic evidence of tumour regression has been observed in most patients, with some complete responses.

Brachytherapy has also been reported to be effective in the palliation of previously treated lung cancer, with symptom relief and endoscopic improvement.

There are few comparative studies available, but Stout et al compared a single fraction of brachytherapy with fractionated palliative external beam radiotherapy, reporting comparable symptom relief but a slightly better duration of response for the external beam arm and also a slightly longer survival.

No survival benefit has been demonstrated for palliative treatments. Survival has been related, unsurprisingly, to performance status.

Brachytherapy has been used to treat radiologically-occult early-stage lung cancer. Complete endoscopic responses have been reported in 65–90% of patients, with partial responses in the remainder and 5-year survival of around 80%. Brachytherapy has been shown to be safe and well tolerated, but massive haemoptysis has been reported in up to 7% of patients and is more likely with higher local dosage, combined or re-treatments, or following laser therapy.

Evidence statements
- Brachytherapy is effective in the palliation of inoperable lung cancer. (Evidence level 1)
- Brachytherapy is safe but massive haemoptysis has been reported in up to 7% of patients. (Evidence level 3)
- Brachytherapy may be used to treat early stage lung cancer (Evidence level 3)

Recommendations
- Brachytherapy should be considered for the palliation of haemoptysis or CAO in locally advanced central lung cancer. (Grade D)
- Brachytherapy should not be used first-line in preference to external beam radiotherapy for the palliation of lung cancer. (Grade C)
- Fractionated brachytherapy can be considered for the curative treatment of early central lung cancer, especially if performance or cardiorespiratory status precludes surgery or radical external beam radiotherapy. The success of brachytherapy for radical treatments requires accurate local staging to exclude extrabronchial tumour extension. (Grade C)

Tracheobronchial stents

Principles
Tracheal and bronchial stents can be used to maintain airway patency and integrity. Plastic (ie, silicone) stents and metal...
stents are available. Silicone stents are deployed using rigid bronchoscopy under general anaesthesia. The majority of the published case series regarding outcomes and complications of stent deployment are for deployment by rigid bronchoscopy only.\(^{67}\) Stent deployment using rigid bronchoscopy is not addressed in this guideline. A recent review offers further information.\(^{88}\)

Flexible bronchoscopy is an alternative to rigid bronchoscopy to deploy metallic airway stents. The current standard is the Self-Expanding Metallic Airway Stent (SEMAS), made from the alloy NITINOL (Nickel Titanium National Ordnance Laboratories).

**Technique**

SEMAS are used to treat airway stenosis or aerodigestive fistulae due to malignant disease. Their use is not advised in benign disease because of the high incidence of severe complications with prolonged use.

Before embarking upon a stenting procedure, a stent of the correct diameter, length and type must be chosen. The availability of modern multislice CT scans with multilayer reformats has considerably facilitated this process, making it possible accurately to estimate the length and minimum diameter of the luminal stenosis and the diameter of the adjacent normal lumen. Where a main bronchus is extensively narrowed, the opposite main bronchus can be used to estimate the pre-morbid airway diameter. The length of the stent should be chosen to provide at least 0.5–1.0 cm of overlap at each end of the stenosed segment where possible. The diameter of the stent should be 1–2 mm greater than the estimated normal diameter of the airway. Stent sizing is usually 12–14 mm in diameter for main bronchi, 18–20 mm for the trachea, with lengths of 40 mm for the left main bronchus, 30–40 mm for the right main bronchus and 60–80 mm for the trachea. Where the lesion is exclusively extrabronchial, an uncovered stent is favoured because ventilation of side-branching bronchi can be maintained. For lesions with both extrinsic compression and endobronchial tumour, a stent incorporating a covering membrane (‘covered stent’) is favoured to prevent tumour in growth through the stent after deployment. A selection of stent sizes should be available prior to the procedure in case bronchoscopic inspection leads to a change of chosen stent size.

Some operators favour the insertion of an uncuffed endotracheal tube over the bronchoscope to protect the airway during the procedure. This may reduce trauma to the vocal cords from repeated bronchoscopic intubation and withdrawal during the procedure. After airway inspection a guidewire is introduced through the working channel of the bronroscope and positioned beyond the distal extent of the lesion. The bronchoscope is then withdrawn leaving the guidewire in place. The bronchoscope is reintroduced next to the guidewire. The stent is placed over the guidewire and introduced. The distal end of the stent is advanced beyond the stenosed airway segment. The precise positioning of the proximal and distal ends of the stent can be checked either bronchoscopically or fluoroscopically. When these are satisfactory, the stent can be deployed.

A number of stent deployment devices are available. These all have the stent held compressed radially onto a delivery catheter and held down by a restraining mechanism which may be a silk thread or an external catheter. More recently, metallic carinal Y-stents have become available whose deployment is complex and better performed during rigid bronchoscopy.

**Indications**

SEMAS are used principally for the relief of CAO due to malignant disease. Other indications include malignant airway fistulas and post-anastomosis bronchial strictures following lung transplantation.

**Organisation**

The expertise to deliver airway stenting should exist within each cancer network. It may be provided by thoracic surgeons or respiratory physicians, but should form part of multimodality treatment supervised by a properly constituted cancer multidisciplinary team. It is essential that the team performing the procedures should have appropriate expertise in managing airway complications, should they occur. Safe airway stenting requires the presence of at least two experienced practitioners, one to visualise the endobronchial appearances and one to deploy the stent.

**Complications**

The use of self-expanding metallic stents for the treatment of CAO is associated with a number of complications including stent malposition, migration or fracture, haemorrhage, mucus impaction, overgrowth by granulation tissue or tumour, infection, aerodigestive fistula formation and bronchospasm. Early stent-associated deaths have been reported due to complications such as hypoxia following stent migration, severe sepsis\(^{69}\) and bronchospasm.\(^{90}\) Complications may necessitate stent removal, which can be complex and hazardous where there has been a stent fracture. In benign airway conditions where life expectancy is greater, metallic stents are not recommended because of the longer-term risk of stent fracture.

**Evidence**

The absence of RCTs of airway stenting makes evaluation of its true effectiveness difficult. Nine case series (349 patients) have described the efficacy and safety of stent insertion by flexible bronchoscopy for malignant and benign airway conditions. SEMAS appear effective in improving breathlessness and cough.\(^{90–93}\) A visual increase in airway patency has been documented.\(^{94}\) In a series of 40 patients with malignancy-associated CAO, the severe dyspnoea index improved in 34/39 patients within 24 h of stent insertion.\(^{95}\)

In CAO due to benign causes, stents improve symptoms. In a series of 40 patients this improvement was evident in stridor in 73% of cases, breathlessness in 71%, cough in 79% and in sputum clearance in 75%\(^{96}\). In five series where a proportion of patients had lung function assessed before and after stent insertion,\(^{59} 91–94\) FEV\(_1\), forced vital capacity (FVC) and airway resistance (where measured) improved.

In patients with acute respiratory failure due to malignant CAO requiring mechanical ventilation, stenting is associated with weaning from ventilatory support. In one series this was achieved in 14 of 26 patients with CAO, 21 of whom had malignancy.\(^{95} 96\) These case series data do not permit the identification of stenting as the cause of weaning success.

RCTs are needed to compare the addition of airway stenting to conventional anticancer treatments versus conventional treatment alone in patients with CAO due to malignancy.

**Evidence statements**

- Self-expanding metallic stents are effective in the treatment of malignant CAO following endobronchial debulking techniques. (Evidence level 3)
- Self-expanding metallic stents are effective in the treatment of extrinsic malignant CAO. (Evidence level 3)
Recommendations
- The use of self-expanding metallic stents may be considered for the treatment of malignant CAO due to extrinsic disease. (Grade D)
- Self-expanding metallic stents may be used to maintain airway patency following endobronchial debulking techniques. (Grade D)
- Self-expanding metallic stents can be used to restore or maintain airway patency in conjunction with other treatments such as external beam radiotherapy. (Grade D)

Good practice points
- Patients require careful specialist follow-up after stent insertion. (√)
- Stents should be used with caution in non-malignant disease because of their long-term complications. Self-expanding metallic stents may be difficult to remove following long-term placement. (√)
- Self-expanding metallic stents should only be used in benign disease after all other therapeutic options have been exhausted. (√)
- A risk-benefit assessment should be performed, incorporating immediate and long-term implications, before selecting any particular type of stent. (√)

EMERGING APPLICATIONS FOR FLEXIBLE BRONCHOSCOPY
The following applications have been developed for use with the flexible bronchoscope but are yet to have established a clear place in routine practice.

Electromagnetic navigation bronchoscopy (ENB)
Principles
ENB is an image-guided localisation system to aid biopsy of lesions that are not visible endobronchially. It combines CT-generated virtual bronchoscopy and electromagnetic tracking of a steerable probe within the bronchial tree.

Technique
A multi-slice thin-section CT scan of the thorax is performed and used to create a 3-D virtual bronchoscopy. During virtual bronchoscopy, specific bronchial landmarks such as the main and segmental carinae are identified and the target lesion is marked. At bronchoscopy, the patient lies in a magnetic field created by an electromagnetic board placed below the chest. A magnetic locatable probe, passed through the bronchoscope, is used to mark the same sites in the bronchial tree as were previously identified on virtual bronchoscopy. The two sets of data are then merged to co-register the CT data on the bronchoscopic spatial points. This allows the data from the virtual bronchoscopy to direct the bronchoscopic probe to the lesion. Once the desired location is reached, the locatable guide is exchanged for biopsy forceps or bronchial brushes and sampling is performed.

Indications
- Peripheral nodule sampling
- Targeted biopsy in patients with diffuse lung disease
- Mediastinal lymph node sampling
- Insertion of fiducial markers for radiotherapy
- Implantation of brachytherapy seeds or catheters
- Dye marker placement for surgical resection of peripheral mass

Complications
ENB appears to be safe, with pneumothorax as the most commonly reported complication. The rates of pneumothorax reported in three studies using ENB were 3.5–7.5%, 97–99 which are lower than reported rates of pneumothorax following CT-guided percutaneous needle biopsy.100–102 However, RCTs comparing the techniques have not been performed.

Evidence
The evidence comes from six case series,97–99 103–105 with a total of 231 patients. In these studies a diagnostic rate of 59–80% was achieved. The results indicate that diagnostic accuracy is related to the size of the pulmonary opacity, with greater accuracy for masses >40 mm in diameter.

In a randomised study, Eberhardt et al achieved a higher diagnostic rate by combining ENB with radial EBUS than with ENB alone (88% vs 59%).106 In a separate study they achieved a higher diagnostic rate using suction catheter aspiration (90%) compared with forceps biopsy (50%).107

Studies using virtual bronchoscopy alone to guide peripheral lung biopsy have found similar diagnostic rates,108–110 and there is currently a lack of evidence that ENB provides additional sensitivity.

ENB appears to be a safe and effective but expensive modality for the sampling of peripheral lung lesions.

Recommendation
- Electromagnetic bronchoscopy may be considered for the biopsy of peripheral lesions or to guide TBNA for sampling mediastinal lymph nodes. (Grade D)

Valves in the treatment of emphysema
Principles
Patients with severe emphysema who are on maximal medical treatment are often very disabled. Treatment options other than lung transplantation and, in selected cases, lung volume reduction surgery are limited. This group of patients has significant morbidity with repeated hospitalisations and increased healthcare utilisation. In the UK over 20% of patients with emphysema have severe disease, and in 2004 chronic obstructive pulmonary disease accounted for 1.4 million consultations with over 100,000 hospital admissions.

Endobronchial valves may be used in the treatment of patients with emphysema with severe hyperinflation. The valves are inserted into the target area of the lungs via flexible bronchoscopy under conscious sedation or general anaesthesia. Two different valves are available. The Zephyr valve is a one-way duck-billed valve and the intrabronchial valve (IBV) is an umbrella-like device. Both valves act by reducing gas inflow to the treated segment while allowing air and secretions to exit.

Technique
The procedure may be performed under conscious sedation or general anaesthesia. The insertion of an endotracheal tube at the beginning of the procedure is recommended. Under direct vision, the size of the target airway is estimated. For the Zephyr valve, an appropriately-sized device on its catheter is inserted through the instrument channel of the bronchoscope and the valve is partly deployed. The valve is then wedged onto a carina in the target area to prevent distal or incorrect placement. Once appropriately positioned, the valve is fully deployed. Further valves are placed in order to achieve complete occlusion of the target lobe. Placement of the IBV is similar but requires accurate airway sizing with a calibrated balloon catheter.

Indications
- Heterogeneous (ie, >10% variation) in emphysematous destruction between adjacent lobes on CT scanning
Patients should be enrolled into clinical trials until more evidence is available. (Evidence level 2–)

Indications
Thermoplasty may be indicated in patients with severe persistent asthma receiving high-dose combination inhalers (>1000 μg beclometasone equivalent) plus long-acting bronchodilators or long-term oral corticosteroids. The FEV₁ should be >50% predicted.

Complications
Patients may experience post-procedure respiratory exacerbations. Limited long-term safety data for this procedure are available.

Evidence
The evidence base includes preliminary studies demonstrating feasibility and safety in 25 patients,121 two randomised controlled studies in 146 patients and one randomised sham controlled study in 297 patients.123–125 The studies have consistently demonstrated a transient increase in asthma-related adverse events in the short term during the bronchoscopic treatment, but are associated with a significant reduction in adverse events, asthma-related symptoms and hospitalisations in the longer term. The AIR2 randomised sham controlled study demonstrated a 32% reduction in exacerbations and a decrease of >80% in emergency room visits. There were improvements in quality of life and asthma control symptoms; the mean change in the Asthma Quality of Life Questionnaire (AQLQ) was 1.35 from baseline and 79% of patients had a clinically meaningful improvement in the AQLQ score. There was a reduction of 66% in days lost from work, school and other activities due to asthma.125 However, despite some evidence for the use of thermoplasty in asthma, the studies are selective and the outcomes are only moderately consistent.

Other procedures in emphysema
A number of bronchoscopic procedures are being developed for emphysema that include airway stents (bypass procedure) in homogeneous emphysema, coils which lead to infolding of the lung, hydrofoam gel and steam instillation to induce localised fibrosis.

Bronchial thermoplasty for asthma
Principle
The prevalence of asthma is increasing and ranges from 10% to 13% in the UK. It is associated with a high admission rate of around 200 per 100 000 of the population per annum, and approximately 18% of patients in the UK have severe persistent asthma. Some symptoms are due to airflow obstruction as a direct result of airway smooth muscle contraction. Airway smooth muscle may also have a role in the pathogenesis of asthma by secreting proinflammatory cytokines and promoting airway remodelling. The goal of bronchial thermoplasty is to reduce airway smooth muscle.

Technique
The treatment is performed via flexible bronchoscopy under conscious sedation. Microwave energy is delivered to the bronchial wall via a flexible catheter from a radiofrequency generator. The treatment catheter is passed through the bronchoscope and is navigated to the distal target airway. A wire array at the distal end of the catheter is expanded and the radiofrequency generator activated. This heats the airway wall to about 65°C and selectively ablates the concentric smooth muscle. The airways are treated in a systematic manner from distal to proximal. The right lower lobe is treated first followed by the left lower lobe 5 weeks later, then the upper lobes.

Indications
Thermoplasty may be indicated in patients with severe persistent asthma receiving high-dose combination inhalers (>1000 μg beclometasone equivalent) plus long-acting bronchodilators or long-term oral corticosteroids. The FEV₁ should be >50% predicted.

Complications
Patients may experience post-procedure respiratory exacerbations. Limited long-term safety data for this procedure are available.

positive in some aspects. This is a treatment which might be useful for some selected cases of difficult asthma. The final place of thermoplasty in cases of difficult asthma remains to be established.

Evidence statements

- Bronchial thermoplasty in patients with moderate to severe asthma has been associated with a short-term increase in asthma-related symptoms. (Evidence level 1)
- Bronchial thermoplasty in patients with moderate to severe asthma leads to a reduction in adverse events from 6 weeks after their final treatment. (Evidence level 1)
- Treatment with bronchial thermoplasty in patients with moderate to severe asthma has been shown to reduce the frequency of respiratory exacerbations, days lost from school or work due to asthma and to improve the quality of life. (Evidence level 1)

Recommendation

- Bronchial thermoplasty is a possible treatment option in selected patients with severe persistent asthma already on maximal therapy, although its place in the treatment of asthma remains to be established. (Grade A)

Good practice point

- Long-term safety and efficacy remains unclear. Hence, treatment should be limited to a few specialist centres in carefully selected patients. Longer term follow-up of treated patients is recommended. (D)

CONCLUSION

This guideline provides an evidence-based overview of advanced diagnostic and therapeutic techniques, some of which are widely available and some of which are only available in specialist centres. It is clear that TBNA and EBUS are becoming standard practice in all regions. Tumour ablation is not routinely available and some of which are only available in specialist diagnostic and therapeutic techniques, some of which are widely available and some of which are only available in specialist centres. The availability of that training.

In this rapidly developing field, new techniques and more evidence are going to become available so it is planned to review its current evidence. Chest 2003;123(1 Suppl):1575–683.

APPENDIX 2

A step-by-step practical guide for performing transbronchial needle aspiration (TBNA)

Initial considerations
TBNA requires very few additional resources to implement, and is therefore readily available to all practitioners. Bronchoscopists have, however, frequently found that ‘real-world’ results do not equal those in the published literature. This guide is intended to help shorten the learning curve.

TBNA is best viewed as a team effort. Optimal results depend upon
(i) Familiarity with the needle for both the bronchoscopist and the assisting staff.
(ii) Collaboration with colleagues in cytopathology to ensure optimal specimen preparation.
(iii) Careful pre-procedure discussion with a radiologist to ensure that the bronchoscopist knows where the targets are endobronchially.

The procedure
(i) The procedure described is for lymph node sampling. TBNA can also be used to sample extrabronchial tumour, or to take specimens from deep within necrotic lesions.
(ii) The bronchoscope is positioned over the first target site, and the needle sheath advanced through the working channel. Approximately 5 mm of needle sheath is allowed to protrude from the distal end of the channel.
(iii) The bronchoscope is flexed so that the tip of the needle sheath lies against the airway wall, between the cartilaginous rings, and directed towards the target.

The needle
There are several different TBNA needles available and choice between them is clearly a matter of personal preference and cost. It is recommended that demonstration needles are obtained of different types. Needles with a clear plastic outer sheath have the advantage that the aspirated material can be viewed during sampling, which helps the operator to know that the sample will be adequate. The whole team should practise with the chosen needle so that everyone knows what instructions will be given for advancing and retracting the needle, how and when to apply and release suction, and so on.

The assistant of the following colleagues is gratefully acknowledged:
Nicholas Smith BA(Hons) MSc, Information Support Librarian.
Emma Gibbs, Senior Library Assistant.
Laurel Birchley, Library Assistant.
Rowlands Library, Worcestershire Royal Hospital.

Tuition
There are a number of courses available on advanced techniques in bronchoscopy, which offer hands-on training in TBNA technique. It is strongly recommended that a new operator attends such a course, ideally together with bronchoscopy assisting staff.

The procedure
(i) The procedure described is for lymph node sampling. TBNA can also be used to sample extrabronchial tumour, or to take specimens from deep within necrotic lesions.
(ii) Target lymph nodes are identified from prior CT or PET scanning. If the procedure is being performed for lung cancer staging, a plan is made to sample the highest-station nodes first (i.e., N3 before N2 before N1).
(iii) The bronchoscopy is begun as usual. Once the bronchoscope is within the trachea, lymph node sampling is performed before any other inspection or sampling. If possible suctioning within the airways is avoided, lest any exfoliated malignant cells enter the working channel and contaminate the TBNA sample. If the view is obscured by mucus or blood, the injection of a small quantity of saline is used to clear the optics.
(iv) The bronchoscope is positioned over the first target site, and the needle sheath advanced through the working channel. Approximately 5 mm of needle sheath is allowed to protrude from the distal end of the channel.
(v) The bronchoscope is flexed so that the tip of the needle sheath lies against the airway wall, between the cartilaginous rings, and directed towards the target.
(vi) The needle sheath is anchored within the working channel by one of two methods: operators with large hands may be able to use the little finger to apply gentle pressure to the sheath against the wall of the working channel, while still directing the...
bronchoscope. Others may prefer to ask an assistant to anchor the needle sheath. An advantage for the operator of anchoring the needle oneself is that subtle tactile feedback occurs as the sheath tip moves up and down the airway, ‘bumping over’ the cartilage rings. This may facilitate precise, correct positioning of the sheath tip between the rings.

(xii) The assistant is then asked to advance the needle, using some agreed instruction (eg, ‘needle out’). If the needle is of a type that has a reasonably stiff wire running down it, and if the tip of the sheath is correctly positioned between the airway cartilages, the needle will often pass directly through the airway wall. This is known as the ‘Hub against the wall’ method. If the needle does not penetrate the airway and instead causes the sheath and bronchoscope to recoil, the operator can advance the bronchoscope, with the needle sheath still anchored within the working channel, to attempt penetration with the ‘Piggy back’ method.

(viii) Once the needle has passed through the airway wall, it may be necessary to advance the needle sheath, while carefully withdrawing the bronchoscope, so that more of the needle sheath is visible before sampling begins. Otherwise, as the needle sheath is drawn back to begin the cycle of to-and-fro motion through the lymph node, the airway wall may simply recoil forwards towards the bronchoscope, obscuring the view, before any relative motion between the needle and the lymph node has occurred.

(xix) The bronchoscopist then asks that suction be applied to the needle.

(x) The bronchoscopist then begins to-and-fro motion of the needle sheath, and observes carefully the motion of the needle as it enters the airway wall. It is important to be able to observe definite motion in and out, though care should be taken not to withdraw the needle completely from the airway wall. This takes considerable practice.

(x) During the sampling process it is helpful if an assistant holds the bronchoscope stationary at the nose or mouth.

(xii) With some experience it is possible for the operator to know whether a lymph node is being successfully sampled. If it is, then gooey material, looking a little like pink toothpaste or raspberry ripple ice-cream, is seen entering the needle sheath. If the needle appears to be well-positioned, and satisfactory passes are being performed, but no such aspirate is obtained, it is worth slowly withdrawing the needle and then advancing it rapidly in a jabbing motion. This is because some lymph nodes have a relatively tough capsule that deforms steadily as the needle is advanced, without permitting penetration. A jabbing action can overcome this effect and allow the needle to enter the node, which then yields “goo” as above.

(xii) Once a satisfactory specimen is obtained, the needle is withdrawn by the assistant, in response to a clear and previously agreed instruction from the operator. The needle sheath is withdrawn and the specimen prepared by the assistant.

(xiv) The way that specimens are prepared will depend upon the preference of the local cytopathologist. The options are direct smears, air-dried or fixed with cytological fixative, or both, or simple flushing of the sample into liquid, which may be either saline, cytological fixative or media suitable for RNA extraction or flow cytometry. The best results, in the author’s experience, are always obtained by giving the cytopathology department what it wants.

(xv) Further samples are then taken from the same lymph node station, before moving on to further, lower-stage sites. It is recommended that up to 5 passes are obtained through each node.

Golden rules

There are a few rules that will help to avoid complications and promote success.

(i) The needle should never be advanced unless the tip of its sheath is clearly visible, otherwise the needle may perforate the working channel.

(ii) Always sample the highest-station nodes first.

(iii) Don’t give up if the first few nodes sampled give non-diagnostic results. The learning curve for TBNA is not flat.

(iv) Aim for large (>2 cm short axis) nodes for your first few procedures.

<td>Herth, Felix; Becker, Heinrich D.; Ernst, Armin</td>
<td>Conventional vs Endobronchial Ultrasound-Guided Bronchoscopic Needle Aspiration: A Randomised Trial</td>
<td>2004 Chest RCT</td>
<td>plus plus</td>
<td>200 were included, 100 in each arm</td>
<td>Age- Group A: 55.7 and 55.8 years in EBUS and conventional respectively. Group B: 57.5 and 58.8 years respectively. There were 75 women and 125 men. Regional hospital based study. Ethnic origin, comorbidity and disease status were not mentioned, although they were all referred with undiagnosed mediastinal lymphadenopathy</td>
<td>EBUS guided TBNA was compared with conventional (non-ultrasound guided) TBNA. In this paper EBUS guidance involved localisation of the LN by radial EBUS followed by TBNA. TBNA was not performed in real-time.</td>
<td>There is no duration of follow up as this is a diagnostic study. However, all patients with inconclusive TBNA had a surgical biopsy.</td>
<td>Outcome measures were either a positive diagnosis e.g. malignant cells or a lymphocyte positive specimen, indicating that a lymph node had been sampled.</td>
<td>For subcarinal LNs, the yield from conventional TBNA was 74% compared to 86% for EBUS guided. This was significant (p&lt;0.05). For LNs 2,3,4 the figures were 58% and 84% respectively (p&lt;0.001). Combined data were 71% versus 80% (p&lt;0.05).</td>
<td>None stated</td>
<td>Overall, the data is quite convincing and not surprising. However, this study has not been reported very well. In general, detail is sparse. For example, there were no details of inclusion and exclusion criteria, nor a power calculation. The information from the study is useful, although this technique has been superseded by real time EBUS guided TBNA, which has been proven to provide superior results.</td>

31 patients with tracheobronchial obstruction from non small cell lung cancer 14 Photodynamic therapy 17 ND-YAG laser

Inoperable NSCLC, unsuitable for radical Tx due to poor pulmonary function or adverse staging All male, mean age 67 and 64 respectively all male mean age 65 +/-7 years

Effect of PDT and Nd-YAG laser for the treatment of tracheobronchial obstruction from non small cell lung cancer

PDT therapy versus nd-YAG laser

PDT vs Nd-YAG time to treatment failure: 50 vs 38 days p<0.03. Reasons for stopping treatment: -no response 36 pts; Objective tumour progression n=54, systemic progression n=11, worsening of symptoms n=23; death n=13. Response at one week 43% vs 53%. Response at 1 month 38.5% vs 25.5% (not significant). Adverse events; bronchitis 41 pts photosensitivity 4 in 2 events in 16 pts, usually cough & photosensitivity. Symptom relief: similar in both groups. Airway obstruction improved from 79%

500 days

Symptom relief (cough, sputum, haemoptysis, dyspnoea) and reduction of airway obstruction. Length of time to tumour recurrence at treated site, response of tumour size at bronchoscopy and CT scanning, measure QOL (Karnovsky), time to next local recurrence tumour response, survival and safety.

Diaz-Jimenez JP

**Supported by the Yorkshire Cancer Research Campaign and the Laser Trust (Moghissi) Appeal**

Endoscopic laser therapy in malignant tracheobronchial obstruction using sequential Nd-YAG laser and photodynamic therapy.

Thorax

Qualitative research plus

17

Inoperable carcinoma causing >50% endoluminal obstruction.

Effect of sequential Nd YAG laser and PDT Nd YAG 40-60 watt pulses for 4 seconds in non-contact mode; PDT 4-6 weeks later. poly-HpDP 2mg/Kg, light at 630 Nm, 0.5-2cm cylindrical diffuser, 400mW/cm. Mainly Squamous and adeno-carcinoma, 1 renal metastasis, 1 large cell, 1 adenoid cystic.

Up to 39 months

Mean % increase in lumen 66% (range 40-90%). Complete pathological response in 7 patients, for 3-6 months. All patients had symptomatic improvement. FEV1 improvement 25% (range 0-70%). FVC 28% (range 0-90%). 11 survived 1 year, 8 for 2 years. Median survival 18.5 months (3.39). 95% CI 9.9-29.5.

Moghissi, K.

**None**

Endoscopic therapy in malignant tracheobronchial obstruction using sequential Nd-YAG laser and photodynamic therapy.

European Respiratory Journal

RCT plus plus

36

XR occult carcinoma of the tracheobronchial tree, unsuitable for conventional treatment for various reasons: poor respiratory function (12), cardiac disease (10), multiple lesions (5), age>80 (2), experimental treatment (7).

HbDP PDT 2.5mg/Kg, light at 72 hours, 360-1800 Joules.

No patients lost to follow up. Complete responders followed up from 13 to 72 months, less than complete responders followed up from 37 to 109 months.

Survival, endoscopic response.

None

Survival: 1 yr 92%, 2 yr 81%, 3 yr 74.9%, 4 yr 58% 5 yr 43% 11 had apparent complete response (12 lesions), only 1 after a single course, 8 after 2 courses, 9 after 3-4 courses. 8 complete remissions had no local recurrence at 13-72 months. 4 had local recurrence at 43-54 months. 25 patients (27 lesions) had partial response. 19 had XRT, 6 had surgery. 10 alive at 37-109 months. All partial responders subsequently died but most of unrelated causes. No significant treatment morbidity.

Ono, R.

**None**

Hematoporphyrin in derivate photodynamic therapy in roentgenograph ically occult carcinomas of the tracheobronchial tree.

Cancer

Qualitative research plus

36

XR occult carcinoma of the tracheobronchial tree, unsuitable for conventional treatment for various reasons: poor respiratory function (12), cardiac disease (10), multiple lesions (5), age>80 (2), experimental treatment (7).

HbDP PDT 2.5mg/Kg, light at 72 hours, 360-1800 Joules.

No patients lost to follow up. Complete responders followed up from 13 to 72 months, less than complete responders followed up from 37 to 109 months.

Survival, endoscopic response.

None

Survival:1 yr 92%, 2 yr 81%, 3 yr 74.9%, 4 yr 58% 5 yr 43% 11 had apparent complete response (12 lesions), only 1 after a single course, 8 after 2 courses, 9 after 3-4 courses. 8 complete remissions had no local recurrence at 13-72 months. 4 had local recurrence at 43-54 months. 25 patients (27 lesions) had partial response. 19 had XRT, 6 had surgery. 10 alive at 37-109 months. All partial responders subsequently died but most of unrelated causes. No significant treatment morbidity.

Not specified

Lots of data on each patient in tabulated form. Only 5 of 20 deaths were from recurrent disease. Authors refer to the need for better staging/depth assessment to plan suitable choice of treatment but suggest combined PDT/XRT might give the best outcome.

Funkawa, K.

**Not specified**

Locally recurrent central-type early stage lung cancer <1cm in diameter after complete remission by photodynamic therapy.

Chest

Qualitative research plus

93 patients with 114 lesions. Distinction drawn between lesions <1cm and those greater.

Early central lung cancer

Effect of HbDP PDT

Comparison of response, recurrence, and survival between lesions above and below 1cm diameter

Up to 65 months

Complete response (CR), partial response (PR), recurrence rates and cytological characteristics of the primary tumour and recurrences in relation to depth of initial lesion.

Lessons < 1cm CR 93%, 5-year survival 58%, =>1cm CR 58% =>1cm 59% (p<0.001, CR). Recurrence after CR in 12 of 95 lesions, 9 of 77 lesions <1cm (11.7%), 3 of 18 => 1cm (16.7%). PR in 18 patients, 19 lesions -> surgery 13, Cth 5, XRT 1. Most had recurrence within 12 months.

<td>Okunaka, T.</td>
<td>Lung cancers treated with photodynamic therapy and surgery</td>
<td>1999</td>
<td>Diagnostic &amp; Therapeutic Endoscopy</td>
<td>Qualitative research plus</td>
<td>26</td>
<td>Patients being considered for surgery for NSCLC. PDT used to increase resectability or to reduce the extent of required surgery. Stage IA n=1, IB n=2, IIA n=1, IIB n=6, IIIA n=6, IIIB n=5, IV n=1.</td>
<td>Effect of pre-op PDT on resectability.</td>
<td>An attempt is made to compare with similar patients undergoing surgery alone, but not randomised.</td>
<td>60 months</td>
<td>Inoperable to operable: 4 Pneumonectomy to sleeve lobectomy: 11 to lobectomy: 7 no change. 4.5-year survival of 5 T3 (main bronchus) patients receiving PDT/surgery calculated at 60%, compared with 50.9% for 11 similar patients receiving surgery alone. The survival curves showing several deaths at 0-20 months in the latter group.</td>
<td>Not specified</td>
<td>In addition, the increase in resectability, there is a suggestion that survival compared to equivalent cases undergoing surgery alone may be improved - remarkable if the PDT group have been downstaged by PDT to surgical 'comparability', but not quite clear; can only be regarded as 'observation', but the illustrated example also appears to show a case where lobectomy was successfully achieved in an apparently inoperable situation (by UK standards) even by pneumonectomy. PDT eradicating disease from lateral wall of RMLs and distal trachea, enabling RUL resection.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Usuda J</td>
<td>Photodynamic therapy for lung cancers based on novel photodynamic diagnosis using talaporfin sodium and autofluorescence</td>
<td>2007</td>
<td>Lung Cancer</td>
<td>Qualitative research plus</td>
<td>29</td>
<td>Centrally located early lung cancer defined as in-situ or limited invasion, not beyond bronchial cartilage, endoscopically accessible, Xr occult, no evidence of metastasis. All male patients, mean age 72.3 years, with stage 0 or stage 1 endobronchial squamous cell carcinomas assessed with EBUS.</td>
<td>PDT using NPe6 and a diode laser detection system. IV Talaporfin Sodium, 40 mg/M sq. Laser, 'SAFE-3000', 408 Nm to define tumour margin. Treatment laser/664 Nm, 4 hours later, 100 Joules/cm sq Histol and cytol and 3.2 and 3 months post-Tx + fluorescence re-assessment Autofluorescence bronchoscopy to define tumour margin, and PDT (NPe6 and AlGalnP diode laser)</td>
<td>None</td>
<td>Not clearly stated, but at least 21 months.</td>
<td>CR, PR, recurrence rate, Cytological and histological confirmation of response at 1,2,3,6,9,12 months post treatment and then at 6 month intervals.</td>
<td>CR: 35 of 38 lesions, 33+10mm, 5&lt;10mm, 7 recurrences after CR, at 8-21 months. 1 had surgery, 6 rePDT, only 2 CR, 2 then had XRT, 2 had Chemotherapy. No detailed survival data: all patients were alive. Complete response 93.9% with 9.7% later recurrence for tumours = or &lt; than 1 cm (31 pts) and 80% CR if &gt;1 cm with 100% recurrence.</td>
<td>Supported in part by a Grant-in-Aid for Young Scientists (H) from the Ministry of Education, Culture, Sports, Science and Technology, Japan (MEXT). KAKENHI 18791002</td>
<td>Substantial discussion of fluorescence findings and recurrent disease in terms of different morphology - 'thicker', 'polyposid' and 'nodular' types, e.g. thickened type most unobtrusive to white light, and all recurrent disease was also of this type. Study of 29 pts (38 lesions) of stage 0 or 1 squamous carcinoma assessed with autofluorescence and then treated with PDT. 35-38 lesions showed complete response. Study concluded that PDD system using SAFE-3000 and NPe6 improved the quality and efficacy of PDT and avoided misjudgement of the dose of the photosensitiser or laser irradiation in PDT.</td>
<td></td>
</tr>
</tbody>
</table>
Retrospective and ‘subset’ study design, difficult to critically assess but endoscopic remission rates well demonstrated. Disease due to lead-time bias, but these were T1-2 tumours, not ‘dysplasia’ (5 were reported as Ca in situ however). Supported by Laser Trust Fund (Moghissi) 29 treatments in 21 patients, 6 had 2 treatments, 1 had 3 treatments. Complete response in 100% of patients. 2 months- 5 years + 7 had local recurrence at 6-15 months after first treatment, 15 patients alive at 12-82 months, 5-year survival 50.6%. No comparative data for this rather unusual combination treatment, but results appear to compare favorably with historical experience of ... as radical XRT. Clear potential for randomised comparisons, e.g. with either modality alone or even a three-arm study.

B: Bronchial-thermoplasty in subjects with moderate or severe asthma results in a marginal but clear improvement in asthma control, at the expense of short term adverse events. Bronchial-thermoplasty is safe in patients with moderate to severe asthma and improves asthma control. It appears to reduce the frequency of mild exacerbations, improves quality of life and reduces asthma symptoms. There was also an improvement in symptom free days.

<td>Effectiveness and Safety of Bronchial Thermoplasty in the Treatment of Severe Asthma: A Multicenter, Randomized, Double-Blind, Sham-Controlled Clinical Trial.</td>
<td>2009</td>
<td>American Journal of Respiratory and Critical Care Medicine</td>
<td>RCT plus plus</td>
<td>297 patients randomised; 101 to sham and 196 to thermoplasty</td>
<td>Adults 18-65 with chronic persistent asthma, using inhaled corticosteroids at &gt;1000ug/day (beclomethasone equivalent), and LABA &gt;100ug/day. Upto 10mg/day of oral corticosteroids. Stable medications for 4 weeks pre entry, FEV1 &gt;60%, p&lt;0.05 vs sham/day, AQLQ &gt;0.25. Thirty Multicentre sites in 6 countries. Average age 40 years. Sex: in BT group 81 males &amp; 109 females and in the sham group 38 males &amp; 60 females. FEV1 BT group 77.8 +/- 15.65, sham group 79.7 +/- 15.4</td>
<td>The effect of bronchial thermoplasty</td>
<td>Comparison between treatment with bronchial-thermoplasty and sham treatment</td>
<td>one year</td>
<td>The primary outcome was the difference between study groups in the AQLQ score change from baseline to the average of the 6-, 9-, and 12-month scores (integrated AQLQ). Safety was assessed by reviewing all adverse events occurring during the treatment and post-treatment periods. Secondary outcomes included changes in: AQLQ (absolute and individual domains), ACQ scores, percentage of symptom-free days, symptom scores, morning peak expiratory flow (PEF), rescue medication use, and FEV1. Additional outcomes included severe asthma exacerbations (exacerbations requiring systemic corticosteroids or doubling of ICS dose), percentage of subjects experiencing severe exacerbations, respiratory-related unscheduled physician office visits, emergency department (ED) visits, hospitalizations, and days missed from work/school or other activities due to asthma. The mean change in integrated AQLQ score in the ITT population was greater in the BT group (1.35, 6 1.10) than in the sham group (1.16, 6 1.23; ppsuperiority, 96.0%). During the short term period (i.e. bronchoscopy) there was an increase in adverse events in the treated group (mainly asthma exacerbations). All expected and self limiting. In the post treatment period a significant reduction in adverse events was observed in thermoplasty group. During the post-treatment period, there was a 32% reduction in the rate of severe exacerbations in the BT group compared with the sham group (0.48 vs 0.70 exacerbations/subject/y, respectively; ppsuperiority, 95.5%). Of the BT subjects, 26.3% (50/190) experienced severe exacerbations, compared with 39.8% (39/98) of sham subjects (ppsuperiority 99.0%). In the post-treatment period, subjects in the BT group reported fewer days lost from work/school or other activities due to asthma (1.32 +/- 0.36 d/y) compared with sham (3.92 +/- 1.55 d/y; ppsuperiority, 99.3%). Secondary endpoint measures of morning PEF, symptom-free days, symptom score, and rescue medication use showed an improvement over baseline in both BT and sham groups, although the differences between the groups were not statistically significant.</td>
<td>Well conducted MCRCT - the first of its kind for mechanical devices in asthma control. There is an overall beneficial effect in AQLQ and ED visits, although the severe exacerbation rate was only slightly better for BT than sham (1.02 vs 0.91; ppsuperiority 25.8%) for the whole 52 weeks. The study design and patient perceptions of likely benefit may have reduced the difference of the therapeutic impact. It will have a role in severe asthma management alongside other modalities, although this needs to be defined further. Bronchial thermoplasty in patients with moderate to severe asthma is associated with short term increase in adverse events. These usually consists of an increase in asthma related symptoms. Bronchial thermoplasty in patients with moderate to severe asthma is associated with a reduction in adverse events in the longer term (six weeks after last bronchoscopy onwards). Treatment with bronchial thermoplasty in patients with moderate to severe asthma reduces the frequency of respiratory exacerbations. Treatment with bronchial thermoplasty in patients with moderate to severe asthma reduces the number of days lost from school or work due to asthma. Treatment with bronchial thermoplasty in patients with moderate to severe asthma improves quality of life.</td>

<td>Bronchial thermoplasty for asthma</td>
<td>American journal of respiratory and critical care medicine</td>
<td>2006</td>
<td>Qualitative research</td>
<td>plus</td>
<td>18</td>
<td>Mean age 39 years (range 24-58): 6 male 10 female. FEV₁ 82% predicted ± 13.9. All subjects were 18 yr of age or older and had stable asthma, as indicated by no change in their asthma condition or medication needs in the previous 6 wk. Primary exclusion criteria included respiratory tract infection within the last 6 week; a history of two or more lower respiratory tract infections per year requiring antibiotic treatment; and the use of more than four puffs in a 24-h period of a short-acting 2-adrenergic agonist, such as albuterol 100 µg/puff or equivalent, except for exercise.</td>
<td>effect of bronchial thermoplasty on safety and asthma symptoms</td>
<td>timescale effects (upto 2 yr): 1. safety 2. efficacy 3. bronchoscopic surveillance 4. Asthma control - AQLQ, SAIx, hospitalisations</td>
<td>2 years</td>
<td>timescale effects (upto 2 yr): 1. safety 2. efficacy 3. bronchoscopic surveillance 4. Asthma control - AQLQ, SAIx, hospitalisations</td>
<td>Prebronchodilator FEV₁ (% predicted) was maintained after BT, with no significant change from baseline (82.2 ± 14.0, n = 16) at the 2-yr follow-up (85.7 ± 13.1, n = 15). There were significant increases observed at 12 wk (88.6 ± 16.1, n = 15, p = 0.043) and 1 yr (88.3 ± 17.1, n = 16, p = 0.003). Postbronchodilator FEV₁ (% predicted) was maintained throughout the period, with no significant change from baseline. The prebronchodilator FEV₁/FVC ratio was statistically significantly higher at 1 yr (75.8%) than at baseline (72.7%; p = 0.049). This change was not significant at 12 wk (72.8%) or 2 yr (74.5%) post-treatment. There was no significant increase in the mean postbronchodilator FEV₁/FVC ratios after treatment.</td>

<td>None</td>
<td>17.5 months</td>
<td>Safety, radiographic response, symptomatic response.</td>
<td>28/38 symptomatic patients had a significant clinical response, including 6 complete responses and 3 for duration of life. Symptom control for a median of 6.5 months (1.5-23). 69% reduction of atelectasis or decrease in tumour size, radiographically. Endoscopic: 36% complete response, 22% &gt; 50% reduction, 33% 25-50% reduction. 8 bronchoscopy after treatment was completed, 5 improved, 3 progressed. MFH 3 (7%) 2,12 and 20 weeks all had prev/concurrent radiotherapy. Safety: 4% dysphagia, 4% transient increased symptoms, 2% persistent cough, 8% radiation pneumonitis and 7% fatal haemoptysis. Radiographic response 25/36 (69% partial response); symptomatic response 28/38 (74%); bronchoscoptic response 33/36.</td>
<td>Not stated</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Brachytherapy is safe and effective at relieving endobronchial obstruction from malignant tumours. It is also safe and effective in patients already treated with radiotherapy. Fatal haemorrhage is the most concerning adverse event (7%).
Good control with combination external beam radiotherapy and brachytherapy. Generally safe and provides effective palliation of symptoms. However, it does not appear to prolong disease free interval or survival.

There is a survival benefit in responders. Fatal haemoptysis event rate is... remission even in previously irradiated patients. Study claims a survival benefit however it is not clear on what basis.

Symptom response: 115 patients had symptomatic benefit - 56 considerbaly better (32%), 59 slight improvement (34%) and 29 no better (17%). 18 felt worse (10%).

Bronchoscopic response: 46% complete response, 43% partial response (66%), 23 no response (20%) and 2 progression (2%). Safety: 2 patients developed fistula, 2 patients died from haemoptysis.

Survival, complications including MFH, symptom, response and bronchoscopic response.

Better response for cough in submucosal disease. Brachytherapy improves symptoms in patients with both endobronchial and submucosal disease. Slightly better symptom control was observed in patients with peripheral disease in comparison to central disease.

A very poor-prognosis group. Wordy discussion, wide ranging and quite interesting but not focused on the main issue. Includes a brief summary table of other LDR and HDR series.

The only justification for using this study would be as a reference for other techniques of brachytherapy, source placement and the potential avoidance of repeat bronchoscopies.
Multicentre experience of endobronchial valve placement in 98 patients with heterogeneous emphysema significantly reduced RV by 4.9%, increased FEV1 by 23%. Effect on DLCO did not reach significance. Serious complications in 8 of 98 patients studied including one death.

Emphasys (industry)

Safety of procedure: bronchospasm 4 (6%), arrhythmia, cardiovascular 6 (9%), PaCO2 retention 2 (3%), haemoptysis 1.1%, post procedure in after 30 days, pneumonia 4 (6%). SGRQ change from baseline change compared with baseline at 1 month - 8.1 ad 9.6 (p=0.0001), at 3 months - 6.9 ad 12.9 (p<0.001) at 6 months - 6.8 ad 14.3 (p<0.001). FEV1 no significant change 6MWT no significant change.

Emphasis (industry)

Endobronchial valves with bilateral treatment in patients with emphysema improves quality of life. There were small but not significant improvements in proportion of patients who had meaningful clinical improvement in FEV1 & exercise capacity.

<tr>
<td>Beamis, J. J. F.; Rebeiz, E. E.; Vergos, K.; Shashpaw, S. M.</td>
<td>Endoscopic laser therapy for obstructing tracheobronchial lesions</td>
<td>1991</td>
<td>Qualitative research</td>
<td>plus</td>
<td>269 patients</td>
<td>Obstructing lesions due to malignant or benign disease. Lung cancer 200; metastatic cancer 36; benign tumours 6; stenosis 27. Main symptoms dyspnoea, haemoptysis, cough, post-obstructive pneumonia. Average age 63.5 years. Male 168, female 101.</td>
<td>Ability of CO2 laser or Nd:YAG laser to treat tracheal or bronchial obstruction</td>
<td>None</td>
<td>Up to 90 weeks</td>
<td>Safety, complication rate, relief of symptoms.</td>
<td>Of 400 procedures in 269 patients, significant relief was reported after 313 (78%). No improvement after 87 (21.8%) of procedures. Pre-op x-ray showed partial or total atelectasis in 137 patients. Post op x-ray showed improvement in 70 (51%). One death intra-operatively; 11 died within one week of procedure. For benign disease, 81% got relief and there were no deaths.</td>
<td>Not reported</td>
<td>Outcome data is not well reported. Safety data useful. Nd:YAG laser treatment under general anesthesia or conscious sedation is safe with symptomatic benefit.</td>
</tr>
<tr>
<td>Moghissi K</td>
<td>Endoscopic laser therapy in malignant tracheobronchial obstruction using sequential Nd:YAG laser and photodynamic therapy.</td>
<td>1997</td>
<td>Qualitative research</td>
<td>plus</td>
<td>17 patients with tracheobronchial obstruction</td>
<td>9 males, 8 females. Average age 69 years (range 45-79). All had inoperable primary (16/17) or secondary (1/17) tracheobronchial lesions causing more than 50% endoluminal obstruction. Stage IIIA or IIIB.</td>
<td>Nd:YAG laser for relief of endobronchial obs followed by PDT 4-6 weeks later</td>
<td>None. All patients received laser and then PDT.</td>
<td>up to 48 months</td>
<td>Relief of symptoms, WHO PS, subjective degree of improvement. PFTs, changes in CXR, percentage bronchial opening and path response were also recorded.</td>
<td>Survival: 65% at one year, 47% at two years. Median survival was 18.5 months. Improvement in airway obstruction in all patients; mean change in luminal opening 66% (40-90%). Mean FEV1 25% (0-90%) increase. Mean FVC 28% (0-70%) increase. All patients had symptomatic improvement and at least a partial response and 7 had a complete response for 3-6 months.</td>
<td>Yorkshire Cancer Research Campaign and Laser Trust (Moghissi) appeal.</td>
<td>As with most of these studies all patients in this study received active treatment - there was no control group. However, the size of the benefit and survival suggests that they would have done better than a control group had there been one. The survival times with combined approach (laser and PDT) seem to be better than other series of laser alone.</td>

| Chan, AL. | Nd:YAG laser bronchoscopy. Rigid or fiberoptic mode? | 1990 | Chest                     | Qualitative research       | plus           | 79 patients had 124 procedures performed. 42 patients had procedures undertaken by rigid bronchoscope, 32 had procedures performed by FOB and 12 had combined procedures. | All had symptoms of dyspnoea and majority had haemoptysis. Those with lung cancer had previously had surgery or chemotherapy or RT or considered unsuitable for these treatments. Mean age for those having rigid bronchoscopy was 64.5 years (range 25-82) and those having FOB 63.9 years (range 32-86). Those having combined RB/FOB were older mean 71.9 yrs (p<0.05) No difference in sex distribution Majority of cases treated were malignant. 8 were benign granulomas (no diff between RB or FOB approach). Significantly more cases with RB were proximal and right sided compared with FOB which had a distal left sided predominance. | Ability of Nd:YAG LASER therapy to open an occluded airway using either FOB or Rigid bronch or combination. | Rigid versus flexible bronchoscopy; general anesthesia versus conscious sedation. | At least 1 year | Estimated survival using each approach; complication profile; percentage improvement in endobronchial obstruction post laser therapy; duration of procedure; mean total number of pulses used; total power applied per procedure. | Complication rate: rigid bronchoscopy group- haemorrhage (>50ml) 4; MI 2; cardiac arrhythmia 2; flexible bronchoscopy- haemorrhage 3; cardiac arrhythmia 2; bronchopleural fistula 1; mediastinitis 1. Percentage improvement in endobronchial obstruction (rigid vs flexible) trachea 56% vs 47%; R proximal 53% vs 36%; distal 13% vs 56%; L proximal 56% vs 38%; L distal 3% vs 31%. In RB group majority of cases were right proximal and distal (sig diff p<0.001) from FOB group. Mean duration 2.5 hours with RB and 3.5 with FOB. Mean total number of pulses per procedure was significantly higher for RB group compared with FOB group (p<0.001). Total power applied showed no difference. Use of RB significantly improved airway calibre when right or left proximal lesions were involved (p<0.05) and FOB sig improved airway calibre for Right (p<0.05) and left distal lesions (p<0.05). No difference in complications. Survival in RB group 25% alive at 612 and 14% at 1 year compared with 19% and 6% respectively in FOB group. Median length of survival in RB group was 15 weeks compared to 9 months for FOB group. No significant survival differences between any group. | Laser treatment in safe under both general with rigid bronchoscopy and local anesthesia with flexible bronchoscopy. Better restoration of airway patency in patients with central tumours with rigid bronchoscopy and better restoration with flexible bronchoscopy when obstruction was more distal. | Not stated | 23

<td>Do airway metallic stents for benign lesions confer too costly a benefit?</td>
<td>Qualitative research</td>
<td>plus</td>
<td>35</td>
<td>35 adult patients (17 female) deemed unsuitable for surgery or declining surgery and presenting with central airway obstruction from benign causes resulting in the placement of 82 self-expanding metallic stents.</td>
<td>Mean age 59.5 +/- 14.3 years.</td>
<td>Median follow-up 473 days. Mean duration of stent survival within patient 616 days (range 1-3205 days).</td>
<td>Improvement in symptoms of stridor, respiratory distress cough and secretion clearance (none of these further defined in the paper). Compllications: major (requiring an intervention or having a significant clinical impact) and minor; early (less than 24 hours after stent placement) and late. Type of stent deployed.</td>
<td>Improvement in stridor (73%), respiratory distress (71%), cough (79%) and secretion clearance (73%). One or more complications occurred in 28 patients (80%). There was at least one major complication in 16 patients (46%) and at least one minor complication in 27 (77%). Early complications occurred in 3 patients (9%) Temporary glottic oedema n=1 Sustained hypoxia requiring CPAP n=1 Stent migration n=1. Late complications occurred in n=27 (77%) of patients Major late complications in 13 (33%) Obstructive granuloma in 20 (24.4%) stents in 10 (26.8%) patients Stent fracture in 16 (19.5%) stents in 6 (17.1%) patients</td>
<td>Not described.</td>
<td>Self-expanding metallic stents can be used in inoperable benign airway stenosis with caveats based on this single centre case series opinion.</td>
</tr>
<tr>
<td>Hautmann, Hubert; Bauer, Martin; Pfifer, Klaus J.; Huber, Rudolf M.</td>
<td>Flexible bronchoscopy: A safe method for metal stent implantation in bronchial disease</td>
<td>Qualitative research</td>
<td>plus</td>
<td>34</td>
<td>51 patients attending a teaching hospital. Mean age 58.8 +/- 12.3 years. Indications: dyspnoea 53%; retention pneumonia 17%; sputum retention 15% dyspnoea and stridor 12%, lung abscess 3%, Malignant disease in 84%, benign collapse in 16%. 65 stents placed (28% under topical anaesthesia, 72%=48 patients with IV sedation). 73% of malignant obstructions were extrinsic, remainder were exophytic or combination.</td>
<td>Efficacy and safety of metallic stent placement through a flexible bronchoscope</td>
<td>Lung function parameters (FEV1, PEFR, PEF, FEV1/FVC %) and blood gases before and 72 hours after stent insertion.</td>
<td>Clinical improvement (not otherwise defined). Complications of stent insertion.</td>
<td>FEV1, improvement 1.57 to 1.99 p=0.019; PEFR 2.9 L/S - 4.1L/S p=0.001; Raw 0.644kPa.L.s-1 to 0.39 P=0.004; PEF 60-70mmhg to 69.4 p=ns, PEF 34.7mmhg to 32.9 p=ns. Clinical improvement following 52 out of 65 stent implantations. Complications occurred following 20/65 stent insertion procedures, 3 fatal and 17 non-fatal. 3 deaths between 24 hours and 30 days post implantation: 1 at 24 hours due to displaced stent causing asphyxia, 1 from septic shock complicating stent occlusion by mucus, and 1 due to massive haemoptysis. Non-fatal complications: poor stent positioning 7 cases, wrongly sized stent 3 cases, leading to stent migration in 2, stent migration in 8 other cases, hypotension 2 cases.</td>
<td>No information supplied.</td>
<td>Reasonably sized retrospective review of earlier metallic stents at a single centre. Metallic stents can be placed safely by flexible bronchoscopy in malignant and benign airway stenoses/collapse, with demonstrable airway improvement. It also addresses the use of anaesthesia, high frequency jet ventilation and type of stents.</td>

<td>Sutedja G</td>
<td>Endobronchial Electrocautery is an Excellent Alternative for Nd: YAG Laser to Treat Airway Tumors</td>
<td>1997</td>
<td>Journal of Bronchology</td>
<td>Qualitative research minus</td>
<td>56 patients with intraluminal tumours suitable for debulking with Nd:YAG were recruited</td>
<td>45 men, 11 women, median age 64 (range 20-90). 37 patients had intraluminal NSCLC, 19 had other tumours including carcinoid and hamartomas.</td>
<td>Could electrocautery be used for intraluminal tumour clearance.</td>
<td>These would have been cases that would normally have been treated by Nd:YAG, the study assessed whether electrocautery could be used instead.</td>
<td>Not documented</td>
<td>Successful clearance of intraluminal tumour, the need to convert procedure to Nd:YAG.</td>
<td>N/A</td>
<td>Not reported</td>
<td>This is a case series of 56 patients with visible intraluminal tumour who would normally be laser candidates. Instead they had diathermy with conscious sedation (apart from 9 patients with carcinoid who were done under GA) and tumour clearance was achieved in 70%. The remainder proved to have extraluminal disease. 1 patient required laser to achieve deeper necrosis. Complications- 1 patient required rigid bronchoscopy to control haemorrhage. Good qualitative data demonstrating, electrocautery is equally effective as Nd:YAg laser in intraluminal tumour clearance. The authors also suggest that electrocautery is a more cost-effective technique.</td>
</tr>
<tr>
<td>Sutedja G</td>
<td>Fibreoptic bronchoscopic electrosurgery under local anaesthesia for rapid palliation in patients with central airway malignancies: a preliminary report</td>
<td>1994</td>
<td>Thorax</td>
<td>Qualitative research minus</td>
<td>17 patients with a median age of 65 (range 48-83) years. All patients had advanced inoperable tumour and had a poor performance status.</td>
<td>17 patients with intraluminal tumour.</td>
<td>Is fibreoptic bronchoscopic electrocautery an effective mode of rapid symptom relief in patients with intraluminal tumour?</td>
<td>N/A</td>
<td>Survival data recorded up to 11 months. treatment session continued until &gt;75% reopening of lumen or 30 minutes treatment time. Patients asked about symptom s prior to discharge (2-5 days post treatment</td>
<td>Restoration of &gt;75% of lumen diameter, improvement in symptoms of dyspnoea and haemoptysis, lung function and ABGs.</td>
<td>N/A</td>
<td>Not reported</td>
<td>Clearance of tumour to improve lumen diameter to &gt;75% was achieved in all patients with intraluminal obstruction. Physiological measures were not available in all the patients however there was no major deterioration in lung function. Electrocautery appears to be a safe and effective method of palliating symptoms of obstruction due to tumour.</td>

<td>Asano, Fumihiro; Matsuo, Yoshihiko; Shinagawa, Naofumi; Yamazaki, Koichi; Suzuki, Toshitaka; Moriya, Hiroshi</td>
<td>A virtual bronchoscopic navigation system for pulmonary peripheral lesions</td>
<td>2006</td>
<td>Chest</td>
<td>Qualitative</td>
<td>plus</td>
<td>37 patients with 38 pulmonary lesions</td>
<td>Diagnostic accuracy of ultrathin bronchoscopic biopsy using virtual bronchoscopic navigation. Confirmation of diagnosis by other method not reported, except 10 cases of inflammation which shrank or disappeared during follow-up.</td>
<td>N/A</td>
<td>Sensitivity / specificity / PPV / NPV / accuracy</td>
<td>N/A</td>
<td>Ultrathin bronchoscope guided to planned route 94.7%. Forceps advanced to lesion 86.8%. Diagnostic rate 81.6%. For fully diagnosed lesions (37 of 38), sensitivity 81.8%, specificity 100%, negative predictive value 78.9%, positive predictive value 100%, accuracy for malignant disease 89.2%.</td>
<td>Not reported, but navigation system is Olympus prototype.</td>
<td>In 37 patients with small peripheral lesions virtual bronchoscope navigation can be used to guide forceps to the site of a lesion in 86.8% of cases with a diagnostic rate of 81.6%. No comparison attempted with conventional techniques. Historical comparison from literature only. RCT needed. Exam time median 24.9 mins (range 11.6-58.2)</td>

| Jones, Catherine M.; Athanasiou, Thanos; Nair, Sujit; Aziz, Omar; Parkevans; Casula, Roberto; Glenville, Brian; Darzi, Ara | Do technical parameters affect the diagnostic accuracy of virtual bronchoscopy in patients with suspected airways stenosis? | 2005 | European Journal of Radiology | Systematic Reviews and Meta-analyses | plus plus | Overall diagnostic performance, pooled sensitivity and specificity, AUC and odds ratio. Results are meaningful. Virtual bronchoscopy performs well in the investigation of patients with suspected airway stenosis with high overall sensitivity, specificity and odds ratio for diagnosis. Diagnostic power for stenotic lesions using virtual bronchoscopy compared to | Pooled sensitivity 83% (95%CI: 77-91%) Pooled specificity 87% (95%CI: 81-92%) AUC 0.947 | VB is accurate for diagnosis of stenotic lesions. Technical parameters within range of studies make no significant difference to accuracy. Relevant to professionals and policy-makers. | Second meta-analysis from same group published in 2005 with very slight differences in study selection, and slightly different focus (studies of patients with suspected airway stenoses, focusing on importance of technical parameters). Studies of patients with known bronchial stenoses excluded unless blinded comparison with control groups. Adult population. Included if data given on technical CT parameters; pitch, collimation, reconstruction interval, rendering method and scanner type. Additional studies (Jacquez, 2004, Hoope 2004, Polverosi 1998) not included in first meta-analysis. Study adds little to previous meta-analysis, but confirms accuracy for stenotic lesions and shows no effect of technical CT parameters.
Flexible bronchoscopy, using ROC analysis, on accuracy.
