ORIGINAL ARTICLE

Lung irradiation induces pulmonary vascular remodelling resembling pulmonary arterial hypertension

G Ghabadi,1,2 B Bartelds,3 S J van der Veen,1,2 M G Dickinson,3 S Brandenburg,4 R M F Berger,3 J A Langendijk,1 R P Coppes,1,2 P van Luijk1

ABSTRACT

Background Pulmonary arterial hypertension (PAH) is a commonly fatal pulmonary vascular disease that is often diagnosed late and is characterised by a progressive rise in pulmonary vascular resistance resulting from typical vascular remodelling. Recent data suggest that vascular damage plays an important role in the development of radiation-induced pulmonary toxicity. Therefore, the authors investigated whether irradiation of the lung also induces pulmonary hypertension.

Methods Different sub-volumes of the rat lung were irradiated with protons known to induce different levels of pulmonary vascular damage.

Results Early loss of endothelial cells and vascular oedema were observed in the irradiation field and in shielded parts of the lung, even before the onset of clinical symptoms. 8 weeks after irradiation, irradiated volume-dependent vascular remodelling was observed, correlating perfectly with pulmonary artery pressure, right ventricle hypertrophy and pulmonary dysfunction.

Conclusions The findings indicate that partial lung irradiation induces pulmonary vascular remodelling resulting from acute pulmonary endothelial cell loss and consequential pulmonary hypertension. Moreover, the close resemblance of the observed vascular remodelling with vascular lesions in PAH makes partial lung irradiation a promising new model for studying PAH.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a severe and progressive form of pulmonary hypertension that leads to right heart failure and premature death, and no cure is available.1 PAH is characterised by typical angioproliferative lesions, such as neointimal lesions, leading to increased pulmonary vascular resistance.2 The elevated pulmonary vascular resistance leads to high right ventricle systolic pressure and subsequent right ventricular hypertrophy (RVH) ultimately resulting in heart failure.3,4 The pathogenesis of the increased pulmonary vascular resistance is due to a combination of sustained vasoconstriction, arterial wall remodelling and thrombosis.5 Although the typical histopathology of the angioproliferative lesions is well described, the mechanisms are so far unknown. A variety of animal models have been developed to study the mechanism of development and maintenance of pulmonary hypertension. However, few of these models fully describe human PAH.6 Interestingly, we recently showed in a preclinical model that thoracic irradiation also leads to vascular damage, which is the predominant histological change after irradiation of large volumes with a relatively low dose.7 Our findings agreed with suggestions from clinical8 and preclinical studies,9 indicating that treatment of large lung volumes even at a low dose is an important risk factor in the development of pulmonary toxicity. Moreover, whole thoracic irradiation with a sub-lethal dose was shown to induce increased pulmonary vascular resistance and a decrease in pulmonary arterial distensibility and vascular density early after radiation.10 These features seem similar to those observed in patients with pulmonary hypertension.11 Interestingly, patients already suffering from pre-existing pulmonary vascular disease, manifesting as subclinical increases in pulmonary artery pressure, are known to have an increased risk for radiation-induced pulmonary toxicity.12 However, the type, evolution and consequences of pulmonary vascular remodelling after radiation are largely unknown. In the present study, we hypothesise that vascular damage after irradiation of the lung may develop into PAH. Using high-precision proton radiation beams, this hypothesis was tested by inducing different levels of vascular damage by irradiating small, intermediate and large volumes of rat lungs with graded radiation doses, resulting in an equal risk of inducing pulmonary dysfunction.13 Since vascular damage plays a central role in radiation-
induced pulmonary dysfunction and pulmonary hypertension, we investigated the commonalities between radiation-induced vascular remodelling and previously described PAH models.

MATERIAL AND METHODS

Animals

Adult male albino Wistar rats (n=78, 270–320 g, 8–9 weeks old) of the Hsd/Cpb:WU strain bred in a specific pathogen-free colony (Harlan-CPB, Rijswijk, The Netherlands) were used in the experiments. They were housed five to a cage under a 12 h light−12 h dark cycle and fed rodent chow (RMH-B, Hope Farms, Woerden, The Netherlands) and water ad libitum. The experiments were performed in agreement with the Netherlands Experiments on Animals Act (1977) and the European Convention for the Protection of Vertebrate Animals Used for Experimental Purposes (Strasbourg, 18.III.1986).

Irradiation technique

To induce different levels of vascular damage, 33%, 50%, 75% or 100% of the rats’ lungs were irradiated to 28, 20/22, 17 and 13 Gy (single fraction) respectively (figure 1). This was done with 150 MeV protons from the cyclotron at the Kernfysisch Versneller Instituut, using the shoot-through technique as published previously.15–16 This results in very sharp lateral field edges (20–80% isodose distance: 1 mm)16 thus sparing the shielded part of the lung very effectively. The irradiation ports (figure 1) were designed using CT scans of animals of the same age and weight.17

Histopathology

For morphometric analysis, tissue samples were taken from in-field and out-of-field of the left lung at a distance of at least 3 mm from the field edge and compared with non-irradiated controls (n=5). The radiation response of the pulmonary vasculature was assessed by evaluating the morphology before (2 weeks post irradiation) and at the peak of pulmonary dysfunction (8 weeks post irradiation)17 in three rats per group. Pulmonary sections (5 µm thick) were stained with haematoxylin and eosin, rat endothelial cell (EC) specific marker (HIS52) or Verhoeff’s elastica stain. Since 70% of the pulmonary vascular bed consists of radiosensitive microvasculature18–19 and damage of these can be expected to have the largest impact on lung function, small intra-acinar vessels (<50 µm) were selected for morphological analysis. For morphometric analysis of the vascular dimensions, lung sections with Verhoeff’s elastica stain were used according to van Albada et al.20 In short, 40 randomly chosen pulmonary intra-acinar vessels <50 µm were assessed at 400× magnification using an image analysis system (CZ KS400; Imaging Associates, Bicester, UK). Two different vascular areas were defined: outer vessel area and luminal area. The outer vessel area was defined as the area within the external elastic lamina. The area within the internal elastic lamina was defined as the luminal area. Areas were transformed into diameters and subsequently wall thickness was defined by subtracting the external diameter from the luminal diameter. Occlusion was then calculated in these pulmonary vessels accordingly, as (outer vessel diameter−luminal diameter)/(outer vessel diameter).

Vessels were excluded from the measurement if they were too elliptical (ratio of the largest and smallest diameter exceeded 2), had an incomplete circular shape, were collapsed along more than one-quarter of the vessel wall or were located adjacent to an airway.

Haemodynamics

To assess the effect of the early radiation response of the lung vasculature on pulmonary/cardiac haemodynamics, right ventricle and pulmonary artery pressure (RVP and PAP) were directly measured at the peak of pulmonary dysfunction, 8 weeks after lung irradiation, according to Rabinovitch et al.21 In short, the rats (n=4 per group) first were anaesthetised (isoflurane) and ventilated with room air. A fluid-filled catheter with the pressure transducer was induced via the right external jugular vein into the right ventricle (RV) cavity and guided to the pulmonary artery (PA) under pressure waveform monitoring to record the RVP and PAP. After completion of the haemodynamic measurement, the thorax was opened and heart and lungs were excised. The heart was divided into atria, ventricles and septum and weighted separately. Right ventricle hypertrophy (RVH) was assessed by measuring the ratio of the weights of RV to the combination of left ventricle and intraventricular septum (IVS). The measurements were compared with non-irradiated controls (n=5).

Breathing rate assay

In preclinical studies, breathing rate (BR) is considered as a surrogate for pulmonary function.17–22 BR was measured before and every 2 weeks after irradiation up to week 10 (n=24 per group), as previously described.17 The increase in the BR at this time, relative to the mean BR in weeks 0–2 after irradiation, was used as an indicator of early pulmonary dysfunction. The BR of non-irradiated controls was available in our database from previous experiments (n=9).

Statistics

To test whether differences exist between groups in pressure measurements and RVH assessment, the post hoc Bonferroni test was performed using one-way analysis if variance. For morphology quantification, the linear mixed model and F-test were specifically used to test differences among quantified parameters when comparing all groups at once. In this test randomly chosen vessels per rat per group were considered as

**Figure 1**: Overview of applied irradiation ports.
Global loss of pulmonary endothelial cells (ECs) precedes parenchymal damage. The effect of lung irradiation on lung tissue and ECs was assessed by evaluation of the morphology of lung tissue by haematoxylin and eosin, and immunohistochemical staining of rat EC specific marker (HIS52) respectively. Lung samples were taken from both in-field and out-of-field 2 weeks after 50% lung irradiation at 20 Gy. (A) A large and small vessel in non-irradiated lung tissue shows an intact endothelial layer; the integrated lining of ECs is shown at a higher magnification. Perivascular oedema (in-field and out-of-field, B and C, respectively; pointed by arrows) and EC detachment (leading to a disrupted endothelial layer) are the predominant damage. The results are representative sections from three irradiated rat lungs.

RESULTS

Global loss of pulmonary endothelial cells precedes parenchymal damage and induces global pulmonary vascular remodelling

At 2 weeks after 50% lung irradiation to 20 Gy, prior to pulmonary dysfunction, the morphology of irradiated and shielded lung tissue was evaluated. In previous work we showed that this irradiation setting results in a comparable level of parenchymal and vascular damage at 8 weeks post irradiation, the peak of pulmonary dysfunction. Indeed, prominent perivascular oedema in large and small vessels was observed in the radiation field (in-field), whereas besides minor changes in the epithelium, no major morphological changes could be observed in the alveolar parenchyma (figure 2A,B). Interestingly, a similar effect was observed in the shielded part of the lung (out-of-field) which received no dose, suggesting a vascular effect throughout the entire lung (figure 2C).

Besides the vascular oedema, loss of cells expressing the rat EC-specific marker HIS52 was observed in-field and out-of-field (figure 2A–C), indicating a global detachment of ECs and disruption of the endothelium in pulmonary vasculature. Since it is well known that changes in the integrity of ECs lead to increased permeability and leakage in irradiated tissues, the early response of pulmonary vasculature to lung irradiation may be initiated from the global lung EC loss. EC injury is a hallmark in initiating/mediating structural changes in pulmonary vasculature. Therefore, the morphology of the lung vasculature was investigated at the peak of pulmonary dysfunction. Lung irradiation-induced structural changes in the vasculature, such as muscularisation of the media layer, thickening of the adventitia and more advanced lesions, including neointimal lesions and obliteration of small pulmonary vessels (figure 3B), were indicative of advanced remodelling of all layers. As expected, due to the global nature of vascular response, these features were also present out-of-field. To check whether the vascular response occurs at lower doses, the morphology of the lungs was evaluated after irradiation of the whole lung with 13 Gy. In previous work we showed that this irradiation setting has the lowest applicable dose which produces a pronounced pulmonary dysfunction. Prior to pulmonary dysfunction, predominant perivascular oedema was observed with no sign of parenchymal damage (see online supplementary figure 1A). At the peak of pulmonary dysfunction again severe vascular remodelling was observed without major parenchymal remodelling (see online supplementary figure 1B). This may...
Figure 3 Early radiation response of lung vasculature leads to global pulmonary vascular remodelling. (A) Anatomy of non-irradiated control pulmonary intra-acinar vessel (<50 μm). Pulmonary vascular remodelling was assessed by immunohistochemical staining (Verhoeff’s elastica stain) of pulmonary intra-acinar vessels 8 weeks post irradiation of 33, 50 and 75% of rats’ lungs to 28, 22 and 17 Gy, respectively. (B) Lung irradiation induces vascular remodelling such as muscularisation, adventitia thickening and neointima formation. (C) Vascular remodelling was present in-field and out-of-field showing a global pulmonary vascular response in all irradiated volumes. indicate that the tolerance dose for vascular response is lower than the parenchymal response.

Global response of pulmonary vasculature is dependent on irradiated volume

Development of pulmonary dysfunction depends on the irradiated lung volume. Therefore, the extent to which pulmonary dysfunction is determined by pulmonary vascular remodelling was assessed by morphological quantification of vascular damage, induced to different levels by irradiating different lung volumes (figure 3C). Strikingly, irradiated-volume dependent increases were observed in absolute wall thickness (figure 4B, p<0.05) and the percentage of luminal occlusion (figure 4C, p<0.05). Vascular remodelling was more pronounced with an increase in irradiated volume despite the lower radiation dose. Moreover, the out-of-field response increased as the irradiated volume increased (figure 4B,C, p<0.05). This indicates a global pulmonary vascular response rather than a response confined only to the area where the radiation dose is deposited.

Global pulmonary vasculature response determines pulmonary dysfunction

Global changes in vascular bed increase the pulmonary vascular resistance and induce elevated RVP and PAP, features that are known as pulmonary hypertension. Indeed lung irradiation was found to induce pulmonary hypertension by showing an irradiated-volume dependent increase in all components of RVP and PAP, despite the decreasing dose (figure 5A). Moreover, as can be expected with an increase in pulmonary vascular resistance and PAP, the increased RV workload led to an irradiated-volume dependent RVH and a decrease in IVS weight (figure 5B). These are generally considered as characteristics of the severity of pulmonary hypertension. Therefore the results showed that rats irradiated to the largest lung volume (75%) even to a relatively low dose (17 Gy) suffer from severe pulmonary hypertension. In addition, as a measure of pulmonary function, the BR of the irradiated animals increased in a similar manner to all other measured parameters, indicating that the development of pulmonary dysfunction is related to pulmonary hypertension (figure 5C). To determine to what extent the global pulmonary vascular response and hence pulmonary hypertension are responsible for pulmonary dysfunction, the increase in BR and mean PAP were correlated using all individual data (figure 5C). Remarkably, a strong correlation of these two parameters (figure 5C, r=0.9) was found. Taken together, our results indicate that the global pulmonary vascular response plays a major role in the development of early radiation-induced pulmonary dysfunction.
DISCUSSION

In preclinical studies pulmonary dysfunction after irradiation of large lung volumes seems to be caused by vascular damage. Since vascular remodelling is a hallmark of PAH, we investigated whether irradiation could induce pulmonary hypertension with the related pulmonary vascular changes.

We show the proof of principle that irradiation of the lung leads to pulmonary vascular remodelling with subsequent pulmonary hypertension and RVH. The pulmonary vascular remodelling induced by irradiation showed striking similarities with the characteristic histopathology of PAH, including EC damage, vascular cell proliferation and neointimal lesions. The first signs of vascular changes such as EC loss and perivascular oedema were observed in the irradiated and shielded parts of the lungs. For each group three rats and for each rat two fields (in-field and out-field) and for each field 40 randomly chosen vessels were used for the morphological quantification. The outcome from each group was subtracted from the outcome of the control group and then represented in the graphs. The data are presented as mean±SEM. A significant difference between groups was found at p value <0.0000001. L, luminal diameter; O, outer vessel diameter.

Figure 4 Early radiation response of lung vasculature depends on irradiated volume rather than on local dose and is a global effect in the lung. (A) An example of quantification of vascular response in lung tissue in-field and out-of-field from different irradiated volumes 8 weeks post irradiation. A large overview of the lung tissue was shown with arrows pointing at remodelled pulmonary intra-acinar vessels (<50 μm). Two vessels were chosen to show the procedure of quantification by measuring the absolute wall thickness and the percentage of luminal occlusion. This quantification was applied for 40 pulmonary intra-acinar vessels per rat per field (in-field or out-of-field) and the average of the obtained values was used as an assessment of the vascular response of that particular lung tissue. (B, C) Early pulmonary vascular response depends on irradiated lung volume and is a global effect in the lungs. For each group three rats and for each rat two fields (in-field or out-field) and for each field 40 randomly chosen vessels were used for the morphological quantification. The outcome from each group was subtracted from the outcome of the control group and then represented in the graphs. The data are presented as mean±SEM. A significant difference between groups was found at p value <0.0000001. L, luminal diameter; O, outer vessel diameter.

in our study suggests that in our model the reduced ventilatory efficiency as a consequence of reduced perfusion is responsible for the increases in BR, as frequently observed in patients with PAH. Hence in this model of PAH in rats, BR may seem to be a sufficient surrogate measure of pulmonary function.

The acute EC loss and perivascular oedema found in the current study may result from ECs detaching from the basal lamina, loss of endothelium integrity due to EC retraction and increased permeability to low molecular weight solutes shown to occur hours to days after radiation of pulmonary ECs. Although not yet studied in lungs, the importance of acute EC loss in the development of radiation-induced normal tissue damage has been established for other tissues such as intestine, spinal cord and rectum.

In patients treated for rectal cancer with preoperative radiotherapy the radiation injury to normal tissue correlated strongly with the radiation-induced vascular damage as quantified by vascular wall thickness. The same study also demonstrated that irradiated ECs induce migration and proliferation of vascular smooth muscle cells, an important feature of vascular remodelling in PAH. It therefore seems that ECs may be the main target of radiation in many organs and may have a pivotal role in the development of early radiation-induced vascular changes in the lung. However, the current study shows for the first time that this phenomenon can induce pulmonary hypertension and function failure. Indeed in many pulmonary vascular
diseases, such as PAH, EC dysfunction is considered to play an initiating role in the pathogenesis of vascular remodelling. The features of vascular remodelling in our model show striking similarities with those observed in other experimental pulmonary hypertension models using the same strain of rats of the same age, or Sprague Dawley rats with almost the same age and weight (300–350 g). This supports the hypothesis that EC loss also plays an initiating role in the pathogenesis of the early radiation-induced vascular changes in the lung. Moreover, in other animal models observations in line with ours have been published after thoracic irradiation, such as acute vascular remodelling in August rats and increased mean pulmonary artery pressure in Sprague Dawley rats, dogs, and sheep. Therefore, our findings have opened up a new way of studying the radiation model of pulmonary hypertension to better understand EC dysfunction and degeneration of vasculature in pulmonary vascular disease leading to PAH, a disease in which the inducing mechanisms are not completely understood.

One of the most striking observations in this model of radiation-induced pulmonary vascular damage is that the histomorphology shows the development of neointimal lesions, which are considered hallmarks of PAH. Treatment of patients with PAH, in the international classification type I PAH, still have a poor prognosis despite improvement in therapeutic regimens, hence it is referred to as the ‘irreversible’ form of PAH. Irreversibility of pulmonary hypertensive disease has been specifically associated with the presence of these neointimal lesions. Although many PAH models have been shown to develop medial hypertrophy, few models have been described that consistently develop neointimal lesions. In the current era, neointimal models are needed to adequately study the pathobiology of PAH and the effects of new treatment strategies. The occurrence of actual neointimal lesions in this radiation-induced pulmonary hypertension may offer such a novel model. A unique feature of the radiation-induced model is the dependence of irradiated lung volume on the induction of damage and consequent changes in PAP, which facilitates well controlled induction to predetermined levels of PAH to study different stages of disease development in a controlled manner.

Radiation-induced EC loss (eg, due to apoptosis) and the consequent disruption of endothelial lining with increased permeability and perivascular oedema shown in this model may decrease the blood flow in the irradiated vasculature. As
Pulmonary vasculature

a compensatory effect, the pressure, blood flow and thereby the shear stress would increase in the vasculature in the non-irradiated part of the lungs. This increase of the shear stress may then lead to changes in function and structure of ECs in the non-irradiated vasculature. Indeed, changes in blood flow and shear stress are known to specifically regulate vascular remodelling by altering EC and smooth muscle cell apoptosis and proliferation rates. Increased shear stress induced by increased pulmonary blood flow in patients and animal models with large congenital cardiac shunts is known to lead to pulmonary endothelial dysfunction and progressive vascular remodelling and, thus, flow-associated PAH. This may be a mechanism through which out-of-field EC loss and whole lung vascular remodelling develops. It is expected that irradiation of larger lung volumes even at a low dose (high enough to induce EC apoptosis) induces a more pronounced increase in blood flow and shear stress in non-irradiated vasculatures, leading to an enhanced out-of-field effect. The unique behaviour of our radiation-induced pulmonary hypertension model enables different methods of clinical measurement.

So far, treatment for PAH has focused on the use of epoprostenol, phosphodiesterase inhibitors and endothelin receptor antagonists with limited success. Recently, the use of anti-proliferative agents such as imatinib, a platelet-derived growth factor inhibitor, was suggested to be a new class of drugs leading to improved outcome of patients with PAH. Alternatively, cell-based therapies such as the use of bone-marrow-derived endothelial progenitor cells have recently been introduced in cell-based therapies such as the use of bone-marrow-derived endothelial progenitor cells have recently been introduced.

CONCLUSION

Lung irradiation was shown to induce pulmonary vascular degeneration and pulmonary hypertension possibly initiated from EC loss. As the histopathology of these lesions closely resembles vascular remodelling in PAH, including neonatal lesions, partial lung irradiation may be a promising new model to study and develop strategies for the prevention and treatment of PAH.

Bronchoalveolar lavage-directed therapy does not affect prevalence of *Pseudomonas aeruginosa* infection and structural lung injury in children with cystic fibrosis

Early *Pseudomonas aeruginosa* pulmonary infections lead to increased morbidity and mortality in children with cystic fibrosis (CF). As this diagnosis is difficult to ascertain in the non-expectorating patient, the authors set out to determine if bronchoalveolar lavage (BAL)-directed therapy during the first 5 years of life leads to better outcomes than standard practice (which is therapy based on clinical features and oropharyngeal cultures).

This multicentre, randomised, parallel-group trial recruited patients between 1999 and 2005 from eight CF centres in Australia and New Zealand. Of 267 eligible infants, 36% were excluded. Patients were randomly assigned in a 1:1 ratio to receive either BAL-directed or placebo-directed therapy on *P. aeruginosa* respiratory-related admissions in the BAL-directed therapy group. While this may help determine clinical management, it is essential to note that the study was not powered for primary or secondary outcomes, except for a reduced length of hospital stay for non-*P. aeruginosa* respiratory-related admissions in the BAL-directed therapy group. This study did not find any statistically significant differences between groups for any primary or secondary outcomes, except for a reduced length of hospital stay for non-*P. aeruginosa* respiratory-related admissions in the BAL-directed therapy group. While this may help determine clinical management, it is essential to note that the study was not powered for secondary outcomes, and CF-CT scores have yet to be validated as a clinical outcome measure.
