Positional oximetry to screen for pulmonary arteriovenous malformations in HHT

ABSTRACT
Orthodeoxia has been described in patients with hereditary haemorrhagic telangiectasia (HHT) and pulmonary arteriovenous malformations (PAVM), but its usefulness in screening children for PAVMs is unknown. We show here that while oximetry is overall lower in children with significant PAVMs, supine and upright oximetry is of no additional diagnostic value indicating that positional oximetry is not a useful screening test for PAVMs.

To the editor:
Screening for pulmonary arteriovenous malformations (PAVM) is performed in patients with hereditary haemorrhagic telangiectasia (HHT) to avoid complications, such as brain abscesses and stroke. While the clinical usefulness of screening is more controversial in children, international guidelines do recommend screening regardless of age. Orthodeoxia refers to a decrease in oxygen saturation when changing from the supine to upright position. Individual reports have described orthodeoxia as a finding that led to the diagnosis of PAVMs in HHT, but the diagnostic yield of using positional oximetry as a screening test for PAVMs in children is unknown. Studies in adults have shown upright oximetry to be a better predictor of right to left shunting through pulmonary AVMs than supine oximetry. Here, we aimed to assess the utility of pulse oximetry in the upright and supine position as a screening tool for PAVMs in children with HHT.

We retrospectively extracted data from the paediatric HHT database at the Hospital for Sick Children for the time period of 1997–2012. Screening procedures for pulmonary AVMs included an agitated saline echocardiogram and a CT thorax until 2009, when based on the finding that the echocardiogram had 100% sensitivity for detection of PAVMs, CT scanning was limited to patients with a positive echocardiogram. Genetic testing for HHT mutations was performed by sequencing of the endoglin and ALK-1 gene as well as the SMAD-4 gene in patients with negative testing results. Oxygen saturation measurements in both supine and upright position were performed as part of the clinical assessment after a period of at least 5 min of rest for each position.

Data for 209 children were included. Based on the screening procedure results, patients were divided into four groups (table 1): 116 had neither a clinically nor genetically confirmed diagnosis of HHT and were considered controls. Of 33 patients with PAVMs, 14 were considered to be either clinically significant or associated with feeding vessel >2 mm and resulted in an interventional procedure (embolisation); the remaining 19 patients had small PAVMs with feeding vessel <2 mm on chest CT that were followed (embolisation); the remaining 19 patients had small PAVMs with feeding vessel <2 mm on chest CT that were followed and were considered controls. Of 33 patients with PAVMs, 14 were considered to be either clinically significant or associated with feeding vessel >2 mm and resulted in an interventional procedure (embolisation); the remaining 19 patients had small PAVMs with feeding vessel <2 mm on chest CT that were followed and were considered controls. Of 33 patients with PAVMs, 14 were considered to be either clinically significant or associated with feeding vessel >2 mm and resulted in an interventional procedure (embolisation); the remaining 19 patients had small PAVMs with feeding vessel <2 mm on chest CT that were followed and were considered controls. Of 33 patients with PAVMs, 14 were considered to be either clinically significant or associated with feeding vessel >2 mm and resulted in an interventional procedure (embolisation); the remaining 19 patients had small PAVMs with feeding vessel <2 mm on chest CT that were followed and were considered controls.
