ABSTRACT

Rationale A low prevalence of asthma and atopy has been shown in farmers and agricultural workers. However, in these workers, a higher prevalence of respiratory symptoms has been reported, in which T helper 1 (Th1) and/or Th17 responses may play a role. Aim We investigated the effect of exposure to dust extracts (DEs) from different farms on airway inflammation and T-cell polarisation in a mouse model and assessed T-cell polarisation in agricultural workers from the same farms. Methods DEs were prepared from settled dust collected at cattle and pig farms and bulb and onion industries. Mice were exposed to phosphate-buffered saline (PBS), DEs, house dust mite (HDM) or HDM+DE via nasal instillation, four times per week during 5 weeks. Hyperresponsiveness, airway inflammation, IgE levels and T-cell polarisation were assessed. Th-cell and T cytotoxic (Tc)-cell subsets were investigated in peripheral blood samples from 33 agricultural workers and 9 non-exposed controls.

Results DEs induced interleukin(IL)-17, IL-1β and IL-6 in mouse lung homogenates. DE-exposed mice had more mixed inflammatory infiltrates in the lungs, and more neutrophils compared with PBS-exposed mice. DEs protected against the HDM-induced Th2 response and methacholine hyperresponsiveness. Interestingly, occupationally exposed humans had higher frequencies of Th cells spontaneously expressing IL-17 and interferon γ compared with controls.

Conclusion Chronic exposure to different types of farm dust induces a Th1/Tc-17 inflammatory response in mice and agricultural workers. This may contribute to the low prevalence of Th2-related diseases but may constitute a risk for other chronic respiratory diseases.

INTRODUCTION

Several studies have shown that farmers and agricultural workers (AWs) have a high prevalence of respiratory symptoms related to chronic bronchitis and COPD.1–3 However, it is well recognised that exposure to farm environments has a protective effect against the development of T helper 2 (Th2)-related allergic diseases.4–7 Dose–response relations have been described for occupational endotoxin exposure in association with protection from atopic sensitisation8–10 and allergic asthma,11 whereas positive associations with increased airway responsiveness12,13 and non-allergic asthma have also been reported.11

In mice, exposure to a mixed farm dust extract from cattle and goat stables protected mice from the development of ovalbumine (OVA)-induced asthma features.12 Moreover, a shift in the T-cell response towards Th1 and Th17 subsets has been observed in mice after repetitive exposure to dust extract derived from pig confinement.13 In humans, exposure to swine confinement induced levels of IL-17 and IL-17 expressing lymphocytes in bronchoalveolar lavage (BAL) fluid.14,15 Interestingly, the Th17 response has been shown to be associated with the development of non-allergic or neutrophilic asthma in transgenic mice overexpressing RORyt.16 Hence, a shifted T-cell response could underlie the observed paradoxical effect of exposure to the farm environment in mice and humans.

Depending on the agricultural sector, the work-related microbial exposure can vary greatly.11,17 However, to date, the effects of agricultural dust exposures from diverse sources on T-cell differentiation and the inflammatory response are unclear. Therefore, we determined whether dusts from two farms (cattle and pig) and two agricultural-related environments (onion and bulb industry) changed T-cell responses and the inflammatory profile in mice. A clinically relevant house dust mite (HDM) murine model of experimental asthma was used to

Key messages

What is the key question?

► What is the effect of chronic exposure to farm environments on T-cell subsets and lung inflammation in mice and men?

What is the bottom line?

► Chronic exposure to farm environments may protect against Th2 responses but induces Th17 responses in mice and men.

Why read on?

► This study reveals that chronic exposure to different types of farm dust induces a Th17 inflammatory response in mice and agricultural workers, which may contribute to the protection against Th2-related diseases but may increase the risk for other chronic respiratory diseases.

investigate the protective effect of different types of farm dust exposure on the HDM-induced allergic airway inflammation. In addition, human Th-cell subsets were assessed in occupationally exposed subjects from the same environmental settings as the dust used in the mouse experiments and compared with non-exposed subjects.

MATERIAL AND METHODS

Animal study design

Specific pathogen-free female BALB/c mice (n=8 per experimental group, 8 weeks old) were anesthetised with isoflurane and intranasally exposed to each different dust extract (DE; details below; DE exposure: 1 mg/mL in phosphate-buffered saline (PBS), 50 μL/day), house dust mite (HDM exposure: 40 μg/day in 50 μL PBS) or PBS (50 μL/day) as a control, four times per week, during five consecutive weeks. To investigate the protective effect of dust exposure, mice were exposed to the combination of HDM and each type of DE. See online supplement (figure S1). Mice had access to standard food and water ad libitum. All animal protocols were approved by the Institutional Animal Care and Use Committee of the University of Groningen (permit number 4788E).

Dust extracts

Settled dust was collected from farms and agricultural industries in the Netherlands, and was extracted applying a protocol adapted from Peters et al. For details, see online supplement. The endotoxin concentrations of the different DEs were assessed using the limulus amoebocyte lysate assay (Lonza) as described previously. Fungal extracellular polysaccharide (EPS) levels were measured using a sandwich ELISA. Observed lipopolysaccharide and EPS levels are presented in table 1.

Table 1 Endotoxin and extracellular polysaccharide (EPS) levels measured in the different types of farm dust extracts at 1 μg/mL

House dust mite

HDM consisted of crushed whole bodies from Dermatophagoides pteronyssinus (Greer Laboratories). The endotoxin content according to the manufacturer was 12.05 sEU/mg.

Assessment of methacholine responsiveness

One day after the last exposure, methacholine (MCh) responsiveness was assessed as changes in enhanced pause (Penh) in conscious, spontaneously breathing animals using a whole-body plethysmography system (Buxco Electronics) as described previously. The concentration of MCh inducing a 200% increase in Penh (PC200) was calculated.

Tissue collection

After 5 weeks of exposure, mice were anaesthetised and sacrificed by cardiac exsanguination. Serum was collected and kept at −20°C until use. The left lung lobe was snap frozen and kept at −80°C until preparation of lung homogenates for cytokine analysis. For details, see online supplement. Right lung lobes were carefully inflated with 0.9 mL 50% Tissue Tek, OCT (Sakura) in PBS, and three of the of the four lobes were snap frozen and stored at −80°C until use, while the smallest right lung lobe was zinc fixed and embedded in paraffin.

Measurement of HDM-specific serum IgE

House dust mite-specific IgE was measured in serum as described previously.

Cytokines

Concentrations of interleukin (IL)-1β, IL-4, IL-5, IL-6, IL-13 and IL-17 were measured in lung homogenates by 6-plex ELISA system (Affinityx), or standard ELISA (eBioscience) for interferon γ (IFNγ).

Semi quantitative evaluation of inflammatory infiltrates

Sections (3 μm) of zinc-fixed and paraffin-embedded lung tissue were stained using hematoxylin and eosin. Semi-quantitative scores for degree of inflammation from 0 to 3 were determined by a blinded reviewer. For details, see online supplement and figure S2.

Immunohistochemistry

Cryosections of lung tissue, 4 μm thick, were stained with specific antibodies to determine the presence of T cells, Th17, T cytotoxic 17 (Tc17), γδ T cells, B cells, neutrophils and macrophages. For details, see online supplement. Eosinophils were determined with peroxidase enzyme histochemistry using diamobenzidine (DAB, Sigma Aldrich) as substrate.

For quantitative analysis, neutrophils, Th17 and Tc17 cells were counted manually and numbers were corrected for the total area of lung tissue section as assessed by morphometric analysis using Aperio ImageScope viewing software V11.2.0.780.

Human study population

T-cell subsets in human subjects were studied in 33 non-smoking Dutch AWs (pig and cattle farmers and onion and flower bulb industry workers), with known high dust and microbial exposure, derived from the follow up of the initial OMeGA study and 9 non-exposed controls derived from the NORM cohort. In the NORM study, healthy never and current smokers were included and extensively clinically characterised (NCT00848406). Ten non-smoking subjects were randomly selected per work environment from the follow-up cohort (with the exception of pig farmers of whom only three non-smokers were available) and nine non-smoking non-exposed controls were matched for age and gender. Hereafter, farmers and agricultural industry workers will be referred to as ‘agricultural workers’ (AWs). The study protocol was approved by the institutional ethics committee and all participants gave their written informed consent.

Sample preparation and in vitro stimulation

Peripheral blood mononuclear cells (PBMCs) were isolated using standard density gradient centrifugation and were stored in aliquots in liquid nitrogen. After thawing, cells were washed and resuspended in warm RPMI1640 with 10% fetal calf serum (FCS) and 8–10×10⁷ cells per well were stimulated overnight with 25 mg/mL phorbol myristate acetate (PMA, Sigma-Aldrich) and 1 μg/mL calcium ionophore (Ca-βo, Sigma-Aldrich) at 37°C, 5% CO₂. Monensin (2 μg/mL, Sigma-Aldrich) was added to each sample to inhibit cytokine secretion. As a control, one sample of

each subject was cultured overnight in complete RPMI at 37°C, 5% CO₂ without stimulation. For details, see online supplement.

Immunofluorescent staining and flow cytometric analysis
After stimulation, the cells were washed in 2% bovine serum albumin/PBS and counted. 10⁶ cells were used for the flow cytometry staining. Flowcytometry data were analysed using FlowJo software V7.6.5 (Tree Star Inc). For details, see online supplement and figure S6.

Statistical analysis
Data are presented as median unless stated otherwise. The non-parametric Kruskal–Wallis test was used to assess whether differences between groups existed, followed by a Mann–Whitney U test for post hoc analysis. Different DE exposures were compared to control, and HDM+DE exposed groups were compared with the HDM-exposed group. All analyses were performed using GraphPad Prism V5.0, and differences were considered statistically significant at two-sided p values less than 0.05.

RESULTS
DE exposure induces IL-17 in mouse lung tissue
To determine the effect of DE exposure on the immune response in murine lung, the presence of Th1 (IFNγ), Th2 (IL-4) and Th17 (IL-17A) cytokines was investigated in lung homogenates of mice exposed to different types of DE or to PBS as control. Mice exposed to all different types of DE had higher levels of IL-17 in the lungs compared with PBS-exposed mice (figure 1C). DE exposure had no effect on IFNγ or IL-4 levels (figure 1A,B).

DE exposure induces Th17 in mouse lung tissue
The source of IL-17 in lung tissue was investigated. All IL-17-positive cells were also positive for CD3, and thus of T-cell origin. Quantitative analysis revealed higher numbers of Th17 cells (CD4⁺/IL-17⁺, figures 2A,C) in the groups exposed to DE than in the PBS-exposed group. Tc17 cells (CD8⁺/IL-17⁺, figures 2B,D) showed a similar pattern although not statistically significant. IL-17-producing γδ T cells were not found (data not shown).

In addition, higher levels of IL-1β and IL-6, cytokines involved in Th17 and Tc17 differentiation were found in lungs of DE-exposed groups compared with the PBS-exposed group (figure 2E,F).

DE exposure induces inflammatory infiltrates and neutrophilic inflammation in mouse lungs
All types of DE induced numerous mixed inflammatory infiltrates in mouse lungs (figure 3A), which were located perivascularly and peribronchiolarly, as well as in the parenchyma. Immunohistochemistry demonstrated these inflammatory infiltrates to be composed of T and B cells, macrophages and neutrophils (see online supplementary figure S3). Quantification of neutrophils revealed that all types of DE induced lung neutrophilia (figure 3B).

Exposure to DE does not increase MCh responsiveness
To assess whether exposure to DE induces changes in lung function, MCh responsiveness was measured. Exposure to all types of DE did not increase MCh responsiveness (see online supplementary figure S4).

All DEs protect against HDM-induced Th2 responses
The effect of different types of DE exposure on the HDM-induced Th2 response was determined. HDM exposure increased the levels of Th2 cytokines IL-4, IL-5 and IL-13 in lung tissue, but this increase was not observed in mice exposed to the combination of HDM plus any type of DE (figure 4A–C). Similarly, numbers of eosinophils and levels of HDM-specific IgE were higher in HDM-exposed mice, while these HDM effects were not present in mice exposed to HDM plus each type of DE (figure 4D,E). Mice exposed to HDM had a lower PC200, meaning increased MCh responsiveness, compared with

Figure 3  (A) Inflammatory scores and (B) numbers of neutrophils in lung tissue from mice exposed to phosphate-buffered saline (PBS) or dust extracts from cattle or pig farm or flower bulb or onion industries (n=6–8 per group) Representative pictures of hematoxylin and eosin-stained lung sections of mice from each exposure group are shown.

PBS-exposed mice (figure 4F). This HDM-induced MCh responsiveness was prevented after DE exposure.

Higher percentages of circulating Th17 and Th1 in AWs
To translate our studies in mice to the human situation, the different Th-cell subsets were compared between AWs from the same environmental settings as the dust used in the mouse experiments and non-exposed controls. Except for age, the main characteristics of the two study populations did not differ (table 2). The main characteristics were similar for the four AW environments.

Th-cell subsets were defined by simultaneous measurement of the intracellular presence of IL-4, IL-17 and IFN-γ in CD8– T cells expressing the early activation marker CD69+ and the presence of the transcription factor Foxp3 in CD8– activated (CD25+) T cells. Please refer to online supplementary figure S5 for gating strategies. Interestingly, AWs had higher frequencies of CD8–CD69+ T cells spontaneously expressing IL-17 (Th17) or IFN-γ (Th1) than controls (figure 5A,B, respectively). In addition, AWs had lower percentages of IL-4+ cells (Th2) within the CD8–CD69+ T cells compared with controls (figure 5C).

Since regulatory T cells (Tregs) play an important role in the downregulation of Th1 and Th2 responses, we investigated the intracellular expression of Foxp3 within the CD8–CD25+ T-cell population. There was no difference in frequencies of Tregs between AWs and controls (figure 5D).

Stimulation with PMA/Ca-Io increased the frequencies of Th cells expressing IL-17 and IFN-γ in AWs and controls, resulting in similar numbers of Th17 and Th1 cells for both groups (see online supplementary figure S7). IL-4 expression was not increased after PMA/Ca-Io stimulation and was similar in AWs and controls (data not shown).

Higher percentages of circulating Tc17 and Tc1 in agricultural workers
Similar to the findings in CD8+ cells, AWs had higher percentages of CD8+ T cells spontaneously expressing IL-17 (Tc17) and IFN-γ (Tc1) than controls (figure 6A,B). Percentages of IL-4+ cells within the CD8+ T cells were not different between both groups (data not shown). Overnight stimulation with PMA/Ionomycin increased the frequencies of CD8+ cells expressing IL-17 and IFN-γ in AWs and controls, resulting in similar levels for both groups (see online supplementary figure S7).

DISCUSSION
This study demonstrates that chronic exposure to different types of DEs induces Th17 responses accompanied by lung neutrophilia and mixed inflammatory infiltrates in mouse lungs. In
addition, all types of DEs protected against HDM-induced Th2 responses, that is, airway eosinophilia, HDM-specific IgE in serum, and IL-4, IL-5 and IL-13 production in the lung tissue. Interestingly, our results from the mouse model are supported by the human data. Occupational organic dust exposure skewed the circulating T-cell population towards the Th17 and Th1 phenotypes compared with controls, while the T reg frequencies were of similar size.

Levels of occupational endotoxin exposure are known to vary greatly depending on the type of work environment or agricultural activity. Previously, we observed a linear dose–response relationship between increased endotoxin exposure and a higher risk of respiratory symptoms, which was dependent on level of exposure but seemed to be independent of work environment. In line with these findings, we show in mice that exposure to DEs from four different agricultural settings induced Th17 differentiation and consequent lung inflammatory infiltrates, and protection against Th2 responses. These settled dust samples are complex mixtures and it is difficult to identify causal agents without considering co-exposure to other relevant

Figure 5 Percentages of circulating (A) interleukin (IL)-17, (B) interferon γ (IFNγ) and (C) IL-4 producing CD3⁺CD4⁺CD69⁺ cells, and (D) percentages of Foxp3-expressing CD3⁺CD4⁺CD25⁺ cells from controls and agricultural workers (AWs). agents. In our study, as a result of the extraction procedure of the dust, a bias towards NaCl-soluble components may have occurred.

Exposure of healthy individuals to dusts from agricultural environments has been shown to result in an intense inflammatory response, characterised by high numbers of neutrophils and lymphocytes in bronchial lavage. Exposures have been shown to result in an intense inflammatory response, characterised by high numbers of neutrophils and lymphocytes in bronchial lavage. Exposure of healthy individuals to dusts from agricultural environments has been shown to result in an intense inflammatory response, characterised by high numbers of neutrophils and lymphocytes in bronchial lavage. This response seems to attenuate over time, but repetitive exposures may lead to chronic respiratory disease. Since IL-17 is known to be involved in the IL-8-dependent attraction of neutrophils to the lung, we hypothesised that IL-17 is involved in the DE-induced inflammatory response. In this study, we showed that chronic exposure to different types of DEs induced IL-17 production in murine lung tissue, which was accompanied by marked lung inflammation. This inflammation was characterised by neutrophilia, inflammatory aggregates, mainly composed of macrophages and B and T lymphocytes, and higher levels of additional inflammatory cytokines (IL-1β and IL-6). These findings are in agreement with other mouse studies using pig DEs. However, the effect of DEs from other types of farms have until now not been described. We show that exposure to other types of DEs induced a similar type of inflammatory response as exposure to pig DE.

We demonstrated the presence of Th17 and Tc17 cells in murine lungs after DE exposure. This indicates that these IL-17-producing T-cell subsets are important in host defence against microbial components present in DE, which is in line with previous studies. Other studies described IL-17 production by γδT cells and neutrophils, which was not observed in our study.

The observed protective effects of DEs in the HDM-induced asthma model support data obtained by previous studies in OVA mouse models for asthma. In these studies, exposure to dust extract, polysaccharides and specific microbes isolated from farm cowsheds also protected against OVA-induced allergic airway inflammation. Mechanisms underlying the observed allergy protection in these studies included upregulation of Th1 cells or induction of tolerogenic dendritic cells, as reflected by increased levels of IFNγ and IL-10, respectively. IFNγ levels were not increased after HDM + DE exposure compared with mice exposed to HDM alone, excluding upregulation of Th1 as the mechanism of protection in our model. Hence, the mechanism of protection in our mouse model remains to be elucidated.

According to the hygiene hypothesis, microbial exposures during childhood are important for the development of a healthy Th1 response, to counterbalance the Th2-biased immune system of newborns. More recent studies have shown that exposures to a farm environment protect from Th2 responses independently from farm childhood. We show here that agricultural workers have higher percentages of circulating Th17 and Th1 cells, while the percentage of Th2 cells was lower in non-exposed controls. These findings support the large amount of literature showing a lower prevalence of Th2-related allergic diseases in farmers and agricultural workers. Besides the increased percentages of Th17 cells in agricultural workers, the percentages of Tc17 cells, a subset of CD8+ T cells that produces IL-17, were also increased. While a skewing of the immune system towards the Th1 subset seems to be protective against allergic diseases, the increase in circulating IL-17+ cells in agricultural workers may be related to the development of chronic respiratory lung disease and possibly related to respiratory infections. Interestingly, levels of IL-17, IL-17-expressing cells were reported to be increased in human BAL fluid after acute inhalation of organic dust in a pig confinement. Although these studies were performed with a low number of individuals (15 and 6, respectively), the induction of IL-17 in BAL indicates that a specific IL-17 response is induced.
by exposure to a farm environment. It should be acknowledged
that no female subjects and no smokers were included in our
study. It is not known whether differences are to be expected in
responses according to gender. As active smoking is known to
affect the immune response, we have restricted our population
to non-smoking individuals.

Interestingly, differences in T-cell subsets between agricultural
workers and controls were only found in unstimulated
cells. These cells reflect the actual T-cell phenotype in the host,
which indicates that circulating T cells from agricultural workers
are different from T cells in healthy controls. After stimulation
with PMA/Ca-IO, higher frequencies of cells expressing the early
activation marker CD69 were found and within this population,
higher frequencies of T cells producing IFNγ and IL-17. Howev-er, after this stimulation, no differences were found
between agricultural workers and controls. This can probably be
explained by the strong stimulation by the protein kinase C activ-
ator, PMA and the calcium ionophore, which could have
induced a plateau in cytokine production in both groups.

In conclusion, this study shows that chronic exposure to various
agriculture environments induces a shift in the T-cell population
towards a Th17/Th1 phenotype. This may on the one hand protect
from allergic disease as shown in our mouse model, but on the other hand may contribute to other chronic lung disease, as suggested by the lung neutrophilia in the same mouse model. It is clear
that the role of IL-17 and Th17 polarization in the agriculture
dust-induced phenotype demands further investigation.

ONLINE SUPPLEMENT

METHODS

Animal study design
8 week old specific pathogen free female BALB/c mice (Harlan, Horst, The Netherlands) were housed in 10 groups of 8 and had access to standard food and water \textit{ad libitum}. Female mice were chosen because, according to our previous study, female mice of this strain have a more prominent response to the HDM model of asthma. More specifically, female mice have more HDM specific IgE, more eosinophils in the lungs and are more responsive to methacholine than male mice.\cite{1} Mice were anesthetized with isoflurane and intranasally exposed to each different dust extract (DE; details below; DE exposure: 1mg/ml in PBS, 50 µl/day), house dust mite (HDM exposure: 40 µg/day in 50 µl PBS) or PBS (50 µl/day) as a control, four times per week, during five consecutive weeks. To investigate the protective effect of dust exposure, mice were exposed to the combination of HDM and each type of DE. Mice had access to standard food and water \textit{ad libitum}. All animal protocols were approved by the Institutional Animal Care and Use Committee of the University of Groningen (Permit Number: 4788E). A volume of 50 µl was chosen as studies on distribution of intranasal instillations in mice have shown that a maximum distribution to the lungs is achieved with this volume.\cite{2}

Dust extracts
Settled dust was collected from 30 cattle and 7 pig farms, and from 2 flower bulb and 3 onions agricultural industries in the Netherlands and were pooled by type of agricultural setting. Pooled dust was extracted applying the protocol from Peters \textit{et al} with some adaptations \cite{3}. Briefly, aliquots of approximately 0.5 gram of settled dust samples collected at farm or in agricultural industries were pooled. Mixed dust samples for each location (cattle, pig, flower bulb and onion)
ranged between 2.5 and 7.5 gram of settled dust and were mixed with glass beads in a 1:5 ratio (dust:beads) in a 50 ml Greiner tube, ~2.5 gram dust/tube. Braun sterile water was added to a volume of 50ml. Samples were then mixed for 5min on end-over-end roller at room temperature and subsequently crushed for 5 minutes in ultrasonic bath with crushed ice and transferred to a glass Erlenmeyer. Then sterile water was added to a final concentration of 10 mg dust per ml. Sodium chloride solution was added to obtain a final concentration of 0.9% followed by shaking for 6 hours on horizontal shaker at room temperature. Then samples were centrifuged at 20,000g/4°C/45min and after centrifugation the dust extract was dialyzed (MWCO 3500) against di-distilled water, sterilized through filtration through a 0.22 um filter and lyophilized. Hereafter, the extracted dust from both farms and agricultural industries is referred to as ‘DE’. Dose responses experiments have been performed by the group of Peters et al. [3] using similar extraction, in which optimal dose was determined to be 50μg/ day (personal communication).

**Lung homogenates**

Snap frozen lung tissue was mechanically homogenized (50% w/v) in 50 mM Tris-HCl buffer, containing 150 mM NaCl, 0.002% Tween-20 (pH 7.5) and a protease inhibitor (Sigma Aldrich). Homogenates were centrifuged at 12000xg for 10 minutes to remove any insoluble material. Supernatants were subsequently stored at -80°C until further analysis.

**Semi quantitative analysis of inflammatory infiltrates**

Sections (3 µm) of zinc-fixed and paraffin-embedded lung tissue were stained for Hematoxylin-eosin. Semi quantitative scores for degree of inflammation from 0 to 3 (the greater the score, the greater the inflammatory infiltration in the lung) were determined by a blinded reviewer. Evaluation of the whole lung tissue present in each slide included the bronchiolar compartment as well as the parenchyma. For representative pictures of each inflammatory score, see figure S2.

**Immunohistochemistry**
To determine the presence of T cells, B cells, neutrophils and macrophages, 4 μm-thick cryosections of lung tissue were stained with hamster anti-mouse CD3 (BD Bioscience), rat anti-mouse CD19 (BD Bioscience), rat anti-mouse GR1 (BD Bioscience) and rat anti-mouse CD68 (AbD serotec) antibodies respectively. To determine the presence of Th17 and Tc17 cells, lung cryosections were stained with a monoclonal rat anti-mouse IL-17 antibody (R&D systems) in combination with a monoclonal hamster anti-mouse CD3 antibody (BD Biosciences), a monoclonal rat anti-mouse CD4 antibody (BD Pharmingen), a monoclonal rat anti-mouse CD8 antibody (BD Pharmingen), or a monoclonal hamster anti-mouse γδ antibody (BD Pharmingen).

**Sample preparation and in vitro stimulation**

Peripheral Blood Mononuclear cells (PBMCs) were isolated by standard protocols using Lymphoprep for AW and Ficoll-Paque density gradient centrifugation for healthy controls. Agricultural workers' PBMC were stored in aliquots of 3 – 7x10^6 cells in liquid nitrogen in a solution of 10% DMSO in Iscove’s Modified Dulbecco’s Medium (IMDM, Lonza, Basel, Switzerland) supplemented with 50U/ml Penicillin/Streptomycin, 10% FCS and 0.1% β-Mercapto-ethanol (Merk, Darmstadt, Germany) until use. 5-10 x10^6 cells from healthy controls were stored in liquid nitrogen in a solution of 10% Dimethylsulphoxide (DMSO, Sigma-Aldrich, Steinheim, Germany), 50% FCS (Invitrogen, New York, USA) and 40% Hank’s Balanced Salt Solution (HBSS, Lonza, Basel, Switzerland). Both isolation and freezing methods were compared and showed difference in PBMC yield, but no influence on T-cell populations (data not shown). Cells were quickly thawed in a water bath and slowly diluted in warm RPMI1640 with 10% FCS to dilute the DMSO avoiding osmotic stress. After washing, cells were resuspended in warm RPMI1640 with 10% FCS and 8-10 x 10^5 per well were stimulated overnight with 25ng/ml phorbol myristate acetate (PMA, Sigma-Aldrich, Steinheim, Germany) and 1 μg/ml calcium-ionophore (Ca-Io, Sigma-Aldrich, Steinheim, Germany) at 37 degrees Celcius, 5%CO₂. Monensin (2 μg/ml, Sigma-Aldrich, Steinheim, Germany) was added to each sample to inhibit cytokine secretion. As a control, one sample of each subject was cultured overnight in complete RPMI at 37˚C, 5%CO₂ without stimulation.
Immunofluorescent staining

After stimulation the cell were washed in 2% BSA/PBS and counted. 10^6 cells were used for the flowcytometry staining and incubated with 0.5% human serum (Lonza, Breda, The Netherlands) to block nonspecific bindingsites. Then, cells were washed and incubated with an antibody cocktail containing FITC-conjugated anti-CD3 (BD Biosciences, Breda, the Netherlands), Krome orange-conjugated anti-CD8 (Beckman Coulter, Woerden, the Netherlands), PECy7-conjugated anti-CD25 (eBioscience, Vienna, Austria) and APCCy7-conjugated anti-CD69 (Biolegend, San Diego, USA) for 30 min in the dark on ice.

Following membrane staining, cells were fixed and permeabilized (Fix/Perm buffer, eBioscience, Vienna, Austria) and washed with cold permeabilization buffer. To block nonspecific bindingsites, cells were incubated for 15 min. with 2% human serum, followed by an antibody cocktail containing Pacific Blue-conjugated anti-Foxp3 (Biolegend, San Diego, USA), PE-conjugated anti-IL-4 (eBioscience Vienna, Austria), Alexa Fluor 647-conjugated anti-IL-17 (eBioscience, Vienna, Austria) and Alexa Fluor 700-conjugated anti-IFNγ (eBioscience, Vienna, Austria). After incubation for 30 min in the dark on ice, cell suspensions were washed twice with cold permeabilization buffer and resuspended in fluorescence-activated cell sorting (FACS) lysing solution (BD Biosciences, Breda, the Netherlands). Multi-color fluorescent staining was immediately measured on a LSR-II flow cytometer (BD Biosciences, Breda, the Netherlands) and analyzed using FACS Diva software (BD Biosciences, Breda, the Netherlands).

Flow cytometric analysis

Flowcytometry data were analyzed using FlowJo software 7.6.5 (Tree Star Inc., Ashland, USA). Because stimulation reduces surface expression of CD4 on T cells, CD4^+ T cells were identified indirectly by gating on CD3^+ and CD8^- lymphocytes. Positively and negatively stained populations were calculated by dot plot analysis, as determined by unstained samples. The appropriate isotype controls for the cytokine (IL-4, IL-17 and IFNγ) staining (mouse IgG1 labeled with PE, AF647, and AF700 respectively) are represented in figure S6.

Figure S5 online supplement:Gating strategies to distinguish T-cell populations. FSC-SSC profile was used to distinguish lymphocytes. Within the lymphocyte population, T lymphocytes were identified using the membrane marker CD3, and within the CD3 population, Tc cells were identified using the marker CD8. The CD3+ cells which were negative for CD8 were considered as being CD4+ cells. Within the CD8+ population, a CD69+ population was selected, and in this population the expression of the cytokines (IL-4, IL-17 and IFNγ) was analysed.
