ABSTRACT

Objectives To test the hypothesis that vascular abnormalities on high-resolution CT (HRCT) would be associated with echocardiographic changes and lung function abnormalities in patients with sickle cell disease (SCD) and the decline in lung function seen in SCD patients.

Methods HRCT, echocardiography and lung function assessments were made in 35 adults, 20 of whom had previously been assessed a median of 6.6 years prior to this study. The pulmonary arterial dimensions on HRCT were quantified as the mean segmental pulmonary arterv/bronchus (A/B) ratio and the summed cross-sectional area of all pulmonary vessels <5 mm in diameter (cross-sectional area (CSA)<5 mm%).

Results The segmental A/B ratio was negatively correlated with FEV1, vital capacity (VC), forced expiratory flow between 25% and 75% of VC (FEF25-75) and arterial oxygen saturation (SpO2) and positively with the residual volume: total lung capacity ratio (RV:TLC) and respiratory system resistance (Rrs). CSA<5 mm% was negatively correlated with FEV1, FEF25-75 and SpO2 and positively with RV, RV/TLC and respiratory system resistance (Rrs). There were significant correlations between cardiac output assessed by echocardiography and the segmental A/B ratio and CSA<5 mm%. Lung function (FEV1 = 0.0004, VC = 0.0347, FEF25-75 = 0.0033) and the segmental A/B ratio (p = 0.347) and CSA<5 mm% (p = 0.001) significantly deteriorated over the follow-up period.

Conclusions Abnormalities in pulmonary vascular volumes may explain some of the lung function abnormalities and the decline in lung function seen in adults with SCD.

INTRODUCTION

Sickle cell disease (SCD) is one of the commonest inherited disorders worldwide, affecting an estimated 300 000 newborns every year. With improved general healthcare, the majority of patients with SCD in developed countries can expect to survive to adulthood. In adulthood, however, SCD can be associated with multiorgan damage, including pulmonary complications. Acute chest syndrome is the commonest cause of death in young adults, and pulmonary dysfunction is a major contributor to morbidity in aging adults with SCD. Lung function abnormalities are common in adults with SCD.2,27 Adults with SCD can suffer from parenchymal lung disease and pulmonary vascular disease or both; affected individuals can suffer premature death. Echocardiographic abnormalities consistent with raised pulmonary artery systolic pressure (PAP) suggestive of pulmonary hypertension occur in approximately 30% of adult SCD patients and are associated with increased morbidity and mortality.8,9 Right heart catheterisation studies, however, have demonstrated that only a proportion of SCD patients have pulmonary arterial hypertension (PH), that is, elevated pulmonary arterial vascular resistance, and it is the presence of PH that is associated with early death.12 Nevertheless, elevated tricuspid valve regurgitant velocities demonstrated by echocardiography and thought to be suggestive of raised PAP are independently predictive of mortality.8,13

We have previously demonstrated that the majority of a cohort of adult patients with SCD had pulmonary abnormalities on high-resolution CT (HRCT).7 The HRCT findings significantly correlated with pulmonary function testing results; in particular, there were correlations between reductions in FVC and FEV1 and the prominence of the central vessels on HRCT. Prominent central vessels were found on HRCT in eight of the nine patients.
with restrictive abnormalities. The prominent central vessels may reflect the raised pulmonary capillary blood volume as a result of chronic anaemia causing an increased cardiac output (CO)\textsuperscript{14} and dilation of the pulmonary vessels.\textsuperscript{15} We have demonstrated in SCD children that the increased pulmonary capillary blood volume contributes to their increased airways obstruction.\textsuperscript{16} Hence, we hypothesised that the central vessel prominence would be associated with echocardiographic changes and lung function abnormalities. The aim of this study was to test that hypothesis by prospectively undertaking HRCT studies, lung function and echocardiographic assessments. A further aim of this study was to reassess the cohort examined 7 years ago\textsuperscript{7} to determine whether any decline in lung function correlated with vascular changes evidenced by HRCT studies.

METHODS
Adults with SCD were assessed between 2009 and 2013. Subjects included in the previous study\textsuperscript{7} had initially been assessed between 2003 and 2005. All participants gave written informed consent.

Lung function assessments
FEV\textsubscript{1}, vital capacity (VC), forced expiratory flow between 25 and 75\% of VC (FEF\textsubscript{25/75}), total lung capacity (TLC), residual volume (RV) and mean respiratory system resistance (R\textsubscript{rs}) were measured.

CT
CT patterns were quantified independently by two thoracic radiologists blinded to the clinical and functional data. The extent and severity of CT abnormalities were recorded in individual lobes, the lingula being considered a separate lobe for scoring purposes. Distal vessel dimensions, including both arteries and veins at the sub-subsegmental level,\textsuperscript{17} were measured using the method of Matsuoka et al.\textsuperscript{18,19} The total summed cross-sectional area for the vessels was then expressed as a percentage of the total lung area of the three selected slices using threshold values between −500 and −1024 HU (cross-sectional area (CSA)<5 mm\textsuperscript{2}) (figure 1). The mean segmental artery/bronchus (A/B) ratio in at least three of four lobes was calculated. CT total lung volume (TLV\textsubscript{CT}) was derived using a proprietary lung segmentation algorithm (figure 2). For the longitudinal analyses, initial and follow-up CT scans were compared.

Echocardiography
Two-dimensional and three-dimensional transthoracic echocardiography was performed according to the international guidelines.\textsuperscript{20} Examinations were performed using digital acquisitions on a Phillips Sonos 7500 ultrasound system. Valvular regurgitation was graded from Doppler determinations of transvalvar flow. Tricuspid regurgitation (TR) was assessed in the parasternal right ventricular inflow, parasternal short axis and apical four-chamber views. A minimum of five sequential complexes were recorded. Continuous-wave Doppler signals of the peak regurgitant jet velocities (TRV) (normal <2.5 m/s) were used to estimate the right ventricular systolic pressures (RVSP) using the Bernoulli equation (ie, 4 × [tricuspid regurgitant jet velocity\textsuperscript{2}]). PAP (normal <25 mm Hg) was calculated as the sum of RVSP and right atrial systolic pressures. CO (normal range 4.0–8.0 L/s) and right-ventricular diastolic volumes (RVDV) (normal range 100–160 mL) were also measured. Right and left ventricular function were assessed by measurement of the tricuspid annular plane systolic excursion (TAPSE) (normal >1.5 cm) and the ratio of early diastolic LV inflow (E) to lateral mitral annulus velocity (e\textprime) measured by tissue Doppler (E/e\textprime) (normal <8). Technically acceptable TAPSE measurements were available in 32 patients and E/e\textprime in 33 patients.

Statistical analysis

Lung function test results

There was a wide variation in the lung function of the cohort (table 1). In total, 28 of the 35 patients (80%) had lung function abnormalities: 8 (23%) had a restrictive abnormality, 6 (17%) an obstructive abnormality, 4 (11%) a mixed abnormality and 10 (29%) an isolated reduction in carbon monoxide diffusing capacity (DLCO). Six patients (17%) had a significant response to bronchodilator; three had an obstructive, one a mixed and one a restrictive abnormality, and none had normal lung function.

HRCT abnormalities

A reticular pattern on HRCT was the most prevalent and extensive abnormality, seen in 26 patients (median extent 0 (range 0–3)). Consolidation was present in nine patients (median extent 0.4 (0–4.2)). Reduction in lobar volume was seen in 19 patients (median severity 1 (range 0–7)). Linear bands were seen in 23 patients (median 1 (range 0–6)) and subpleural curvilinear lines in 9 patients (median 0 (range 0–3)). Subpleural consolidation (n=6), thickened interlobular septa (n=2), infarcts (n=7) and traction bronchiectasis (n=0) were present in a minority of patients and excluded from further analysis. The median pulmonary artery to ascending aorta ratio (PA/AA) was 0.90 (range 0.8–1.30), the A/B ratio 1.30 (range 1.0–2.50) and CSA<5 mm% 0.48 (range 0.22–10.2). The extent of a reticular pattern was positively correlated with the presence of linear bands (r=0.64, p<0.0001) and ground glass opacification score (r=0.42, p=0.0115). The presence of linear bands was positively correlated with subpleural curvilinear lines (r=0.39, p=0.0204), which were positively related to the A/B ratio (r=0.46, p=0.0036). The segmental A/B ratio and CSA<5 mm% were positively correlated (r=0.72, p<0.0001).

HRCT, high-resolution CT; GGO, ground glass opacification; RV:TLC, residual volume:total lung capacity ratio; VC, vital capacity.
Echocardiography results

The median TRV was 2.65 (range 1.19–3.60) (m/s), the median estimated PAP 33.5 (range 9.0–70.0) (mm Hg), the median CO 6.0 (range 3.3–9.1) (L/min) and the median RVDV 93.9 (range 36.7–182.6) (mL). The median TAPSE was 2.30 (1.00–3.95) (cm), and the median E/e’ ratio was 7.60 (4.70–16.60). Significant correlations were observed between CO and the A/B ratio (r=0.41, p=0.0120) and the CSA<5 mm² (r=0.35, p=0.0440), but not with the estimated PAP. There was a correlation of CSA<5 mm² with E/e’ (r=0.45, p=0.009). There was also a correlation of CSA<5 mm² with TAPSE (r=-0.38, p=0.035), but only one subject had an abnormal TAPSE result (<1.5) and thus we cannot comment on the relationship between HRCT indices of vascular dilatation and echo indices of RV dysfunction.

The segmental A/B ratio and the CSA<5 mm² were significantly correlated with the haemoglobin level (r=-0.50, p=0.0021; r=-0.42, p=0.0090, respectively) and the lactate dehydrogenase (LDH) level (r=0.33, p=0.0450; r=0.33, p=0.0492, respectively). The segmental A/B ratio was related to the bilirubin level (r=0.47, p=0.0037) and the CSA<5 mm² to the reticulocyte count (r=0.39, p=0.0167).

Longitudinal analysis

The lung function results of the 20 patients who were reassessed had declined significantly (table 4). There were, however, no significant changes seen in the prevalence or extent/severity of lung parenchymal abnormalities on CT, but both the median segmental A/B ratio and CSA<5 mm² had increased significantly over the follow-up period (table 5). The percentage change from baseline in the A/B ratio correlated negatively with that in FEV₁ (r=-0.330, p=0.0079) and VC (r=-0.487, p=0.0357) and positively with RV:TLC (r=0.557, p=0.0164). Logistic regression demonstrated that a higher CSA<5 mm² at baseline was predictive of a subsequent overall deterioration in HRCT appearance, that is, a gestalt change score of 1 (OR 2.62 (95% CI 1.14 to 6.01) per unit increase in CSA<5 mm²,

Respiratory physiology

disease. There was a negative relationship with vascular dimensions and VC, FEV1, FEF25/75 and SpO2 and a positive relationship with RV, RV:TLC, Rrs(0) and Rrs(1), suggesting vascular dimensions were related to an obstructive defect, VC, FEV and FEF25/75. However, can be reduced in both obstruction and restriction and thus the correlations with markers of vascular dilation and reductions in VC, FEV1 and FEF25/75 may also indicate a relationship between vascular dilation and the development of restrictive lung function.

In our cohort, 23% of patients had evidence of a restrictive lung function defect and 17% had evidence of an obstructive defect. Those results are consistent with those of Santoli et al.21 but differ from those of Kling et al,3 who found a much lower incidence of airflow obstruction. The differences may be due to a number of factors. We used a recently reported ethnic-specific reference range for spirometry,21 whereas Kling et al3 used a Caucasian reference range with fixed correction factors to adjust for ethnicity. We classified abnormalities based on the lower limit of normal based on percentiles recommended by the American and European Thoracic Societies,22 whereas Kling et al used a fixed percentage predicted value to define the lower limit of normal for all lung function indices, which does not take into account that the limits of the normal range vary with age, sex and ethnicity. Furthermore, the classification scheme in the Kling’s study specified that in order to be classified as obstructive or mixed, the DLCO had to be normal, which precluded the possibility that impaired gas transfer coexisted with airway abnormalities.

Restrictive lung function defects, that is, a reduced TLC and RV, were not associated with the extent of ground glass opacification or a reticular pattern and showed only a modest association with linear bands, suggesting interstitial fibrosis may not be the predominant mechanism for loss of lung volume in patients with SCD. Indeed, most CT markers of pulmonary predominant mechanism for loss of lung volume in patients with linear bands, suggesting interstitial fibrosis showed no association with reductions in VC, FEV1, FEF25/75, RV:TLC SpO2, Rrs(0) or Rrs(1). The extent of a reticular pattern was associated with a reduction in respiratory system resistance; we speculate that this might be due to the tracitional effects of areas of fibrosis on adjacent bronchi. Subpleural curvilinear bands were noted in 26% of patients; this is an unusual CT sign, formerly believed to be pathognomonic of early asbestosis.23 Subpleural curvilinear bands have subsequently been described in association with micro-atelectasis in patients with atrial septal defect24 or respiratory muscle weakness25 and as reversible sign caused by interstitial oedema resulting from pulmonary congestion.26 Observations in subjects without lung disease and undergoing lymphography have led to the suggestion that the sign may represent an engorged subpleural lymphatic network.27 Given the presence of a high-output state in SCD, and the correlation of subpleural curvilinear lines with markers of small-vessel dilatation observed in our cohort, it is tempting to speculate that this pattern may be related to interstitial oedema and/or increased lymphatic drainage.

We highlight a decline in lung function over a mean of 6.6 years in adults with SCD. A significant decrease was observed in VC, FEV1, FEF25/75, FEV1:VC and KCOe with a significant increase in RV:TLC. There were no significant changes in the results of the CT assessments other than in vascular dimension assessments, where both the A/B ratio and CSA<5 mm²% significantly increased. Those results suggest changes in pulmonary vascular dimensions may be responsible for the decline in lung function. Furthermore, a greater baseline CSA<5 mm²% was predictive of a more rapid progression of both obstructive (increasing RV:TLC) and restrictive (decreasing TLC) lung disease and an increased likelihood of a deterioration in parenchymal disease, as evidenced on HRCT examination. Our results emphasise the phenotypic heterogeneity of SCD lung disease. The changes in vascular morphology related to obstructive defects and the likelihood of deteriorating interstitial lung disease, suggesting that there may be a shared mechanism involving small pulmonary vessels. Field et al28 demonstrated that bone marrow-derived fibrocytes may be mobilised into the circulation and subsequently extravasate into the lungs of SCD mice. There they function as mesenchymal progenitor cells for the production of extracellular matrix and contribute to the development of fibrosis. Elevated levels of circulating fibrocytes have been observed in humans with SCD.28 We, therefore, speculate that pulmonary vascular engorgement and distension may potentiate extravasation of circulating fibrocytes.

This study has strengths, but some limitations too. A strength of this study was the use of two different quantitative methods for assessing pulmonary vascular morphology, the segmental A/B ratio and CSA<5 mm²%, which yielded similar results. We used ethnic-specific references for spirometric indices, but the static lung volume results were related to reference ranges derived from Caucasian subjects with a fixed correction factor to account for ethnicity. All the study population were African or Caribbean, thus correlations within the cohort and comparisons between results at baseline and follow-up were valid. A limitation is that we did not have right heart catheterisation data for pulmonary artery pressures and resistance, but all the patients underwent the same echocardiographic protocol. Studies have demonstrated a minority of patients with elevated TRV have elevated pulmonary artery pressure. In a recent study, only 8 of 26 patients with elevated TRV at echocardiography had elevated pulmonary artery pressure confirmed by right heart catheterisation29 and similar findings were reported in a larger study with 10.4% of 243 patients with elevated TRV having pulmonary hypertension.30 It should be noted, however, that a TRV of >2.5 m/s (corresponding to an estimated mPAP greater or equal to approximately 2 SDs above normal) does not meet the criteria for right-heart catheter-defined pulmonary arterial hypertension (mPAP >25 mm Hg), which is 3 SDs above normal. The latter corresponds to a TRV of approximately 3.0 m/s, which occurs in only about one-third of patients. Different HRCT protocols were used in our earlier study, and in this study, however, care was taken to ensure that all the images used for comparisons were from anatomically comparable sections. In addition, scoring was undertaken by observers who were blinded to the results of lung function and echocardiography results. The consistent relationship between CSA<5 mm²%, A/B ratio and lung function test results suggests the different protocols did not adversely influence our results. We have shown that, if TLV,CT is measured, volumetric HRCT scans are able to capture both restrictive and obstructive functional abnormalities, providing an alternative method to assess global pulmonary impairment in patients with SCD.

In conclusion, we have demonstrated an association between small-vessel pulmonary vascular dimensions on HRCT reflecting pulmonary vascular volume, lung function abnormalities and echocardiographic estimates of CO and ventricular function in adults with SCD. Our results suggest that abnormalities in pulmonary vascular volumes may explain some of the lung function abnormalities and the decline in lung function seen in adults with SCD.

Lung function assessments

Patients were assessed in the Amanda Smith Pulmonary Function Laboratory at King’s College Hospital NHS Foundation Trust. No subject underwent lung function testing within two weeks of an upper respiratory tract infection or within a month of suffering a vaso-occlusive crisis. A history was taken of past and current respiratory symptoms and medication for respiratory problems. Standing height was measured using a wall-mounted stadiometer (Holtain ltd, Crymych, Dyfed, UK) and weight using electronic weighing scales (Seca ltd, Birmingham, UK).

Measurements were performed using a pneumotachograph based system (Jaeger Masterscreen PFT, Carefusion Ltd, Basingstoke UK). Results were expressed as percent predicted for height, age, and sex using the ethnic-specific reference equations for spirometry-[E1] and the European Community for Steel and Coal Statement of the European Respiratory Society reference equations for lung volumes and gas transfer.[E2] Spirometry, static lung volumes using whole-body plethysmography and transfer factor for carbon monoxide were assessed according to American Thoracic Society/European Thoracic Society guidelines.[E3-E5] The mean respiratory system resistance (Rrs(0)) and frequency dependence of resistance (Rrs(1)) from 5-25Hz were measured using impulse oscillometry and expressed as the percent predicted for height, weight, and age.[E6] The frequency dependence of resistance was assessed using the mean slope of the resistance-frequency
curve over the range 5 to 25Hz. Respiratory resistance was considered to be elevated if Rrs(0) was greater than the upper limit of normal. Spirometry was repeated following administration of a bronchodilator (400µg salbutamol via a MDI and spacer) and a positive response was defined as an increase in FEV$_1$ of greater than or equal to 12% from baseline and an increase of at least 200ml. Oxygen saturation was measured using a pulse oximetry (Masimo Radical 7 and a rainbow probe, Masimo, California, USA).

The predicted values for total lung capacity were reduced by 12%, and residual volume by 7% to correct for ethnicity.[E7] The lower and upper limits of normal were defined as the fifth and ninety-fifth percentiles respectively of the appropriate reference range. Patients were diagnosed as having a restrictive abnormality if their TLC was less than the lower limit of normal (LLN), with a normal FEV1:VC. An obstructive abnormality was diagnosed if the FEV1:VC was less than the LLN with a normal VC, or if VC was less than the LLN with a normal TLC and an RV:TLC greater than the upper limit of normal (ULN). A mixed abnormality was diagnosed if the TLC and FEV1:VC were less than the LLNs.

**Computed tomography**

Patients were scanned on a 64-channel multidetector CT machine (GE 64 VCT Lightspeed machine; GE Healthcare, Waukesha, Wisconsin, USA; 100 kV, Auto mA/Smart mA; pitch
1.375, 0.5 sec tube rotation, beam collimation 40 mm, detector size 0.65 mm). Contrast was injected at a rate of 4-5 ml/s and scanning was performed cranio-caudally with the subject in a supine position and breathing suspended at maximal inspiration. The period of CT scanning was timed to coincide with optimal contrast opacification of the pulmonary arterial tree using bolus-tracking. In the earlier study-[E8] patients had been imaged using a dual-detector CT machine (HiSpeed NX/I; GE Medical Systems, Waukesha, Milwaukee, Wisconsin, USA). Interspaced HRCT images (1.5mm collimation at 10 mm intervals) had been acquired at total lung capacity, in the supine and prone positions. Images were reconstructed using a high-spatial-frequency (bone) algorithm. All CT studies were securely stored on CD for subsequent review.

CT patterns-[E9] were quantified i) to the nearest 5%; ii) on a semiquantitative scale or iii) for their presence or absence, as appropriate. The following CT patterns were quantified to the nearest 5%: i) reticular pattern defined as innumerable interlacing line shadows which, by summation, produce an appearance resembling a mesh; ii) ground-glass opacification (defined as a hazy increased lung opacity in which the visibility of bronchial and vascular margins were preserved); iii) areas of decreased attenuation as part of a mosaic attenuation pattern defined as a patchwork of areas of differing lung densities and iv) consolidation defined as a homogeneous increase in lung parenchymal attenuation which obscures the margins of airway and vessel walls. In patients with consolidation, the extent to the nearest 5% of sub-pleural consolidation was also recorded. For ground glass opacification, a score was assigned based on the observed extent (0=none; 1= <10% extent; 2= 10-50% extent; 3 >50% extent). The following CT signs were scored semi-quantitatively: i) thickening of interlobular septa (0=none; 1= <5 thickened interlobular septa [ILS]; 2= >5 thickened ILS or
<50% pleural surface involved; 3= >50% pleural surface involved or 4 = diffusely thickened ILS), ii) lobar volume loss (0=none; 1=mild or 2=severe). The presence or absence of the following signs were recorded: i) traction bronchiectasis defined as irregular bronchial/bronchiolar dilatation caused by surrounding retractile pulmonary fibrosis in a reticular pattern and/or ground-glass opacification; ii) linear bands of attenuation; iii) sub-pleural curvilinear lines defined as a thin curvilinear opacity of 1-3 mm thickness and lying within one centimetre of and parallel to the pleural surface and iv) pulmonary infarcts defined as a peripheral irregular opacity associated with a linear opacity no more than 2 cm in length. Whole-lung scores were produced by taking the mean of all lobes for signs which had been measured to the nearest 5% and by summing the lobar scores for signs recorded as present/absent. Vascular dimensions were assessed in two ways. First, proprietary electronic callipers were used to measure the widest short axis diameters of the upper lobe apical or apico-posterior segmental arteries and the lower lobe posterobasal segmental arteries together with the widest external short axis diameter of the corresponding segmental bronchi on the same axial image in at least three out of four lobes.[E10] Based on those measurements, the mean segmental artery/ bronchus (A/B) ratio in at least three out of four lobes was calculated.

Distal vessel dimensions, including both arteries and veins at the subsubsegmental level-[E11] were measured using the method of Matsuoka et al.[E12, E13] Three CT slices were selected from each examination. The upper cranial slice was located approximately one centimetre above the upper margin of the aortic arch, the middle slice approximately one centimetre below the carina, and the lower caudal slice approximately one centimetre below the right inferior pulmonary vein. The measurements were performed using the Java-based semi-automated image analysis software ‘ImageJ’ (Rasband, W.S., ImageJ, U. S. National
Institutes of Health, Bethesda, Maryland, USA, http://imagej.nih.gov/ij/, 1997-2012). Before processing, each selected image was smoothed using Gaussian blurring to filter image noise. The lung field was then segmented using a thresholding technique to include all pixels between -500 and -1024 Hounsfield Units (HU) (Figure 1) and the segmented image was converted to a binary image with a window level of -760 HU (Figure 1). The ‘Analyze Particles’ function was then used to count and measure the cross-sectional area of vessels within a range of 0-5 mm\(^2\). The ‘Circularity’ function was then used to select only those vessels running approximately perpendicular to the scan plane based on their apparent shape in the slice image, setting the circularity range to 0.9-1.0. The total summated cross-sectional area for those vessels was then expressed as a percentage of the total lung area of the three selected slices using threshold values between -500 HU and -1024 HU (CSA<5mm\(^2\)).

The segmental A/B ratio has been shown to correlate with pulmonary artery pressure in a mixed cohort of patients with lung disease [E14]. CSA<5mm\(^2\) has been measured in patients with HRCT-defined emphysema due to COPD and has been shown to correlate with pulmonary artery pressure in this group.[E12, E13]

CT total lung volume (TLV\(_{CT}\)), comprising air plus tissue components, was derived using a proprietary lung segmentation algorithm (Apollo, Vida Core Lab Services, Vida Diagnostics Inc, Iowa, USA) which uses a localized and adaptive threshold method to delineate lung tissue on a lobar basis from surrounding tissues (Figure 2). The TLV\(_{CT}\) was not available for the scans obtained in 2003-2005.

For the longitudinal analyses, initial and follow-up CT scans were compared. Two observers identified anatomically comparable sections as judged by vascular and bronchial landmarks on the two CT scans from each individual and recorded their impression of whether the overall appearance of the interstitium on the follow-up scan compared to the initial scan had
deteriorated. Patients who had deteriorated were assigned a ‘gestalt’ change score of ‘one’ and those who did not were scored as zero.

**Statistical analysis**

Data were tested for normality using the D’Agostino and Pearson omnibus normality test. Comparisons, as appropriate, were made with t-tests or Mann-Whitney U tests and paired analyses were performed using paired-sample t-tests or Wilcoxon matched-pairs signed rank tests. In the longitudinal cohort, we used non-parametric tests for baseline-follow up comparisons as we felt that the number of patients was too small too meaningfully perform normality testing. For the descriptive data in the larger cohort (n=35), who were tested once, data were displayed as median (range) to demonstrate the wide range in lung function. On HRCT, whilst GGO score, bands, curvilinear bands, and A/B ratio were not normally distributed, the residuals in all of the final regression models did not differ significantly from a normal distribution (Pearson omnibus normality test p>0.05). The strength of relationships were assessed using the Pearson or Spearman rank correlation. Stepwise linear regression with backward elimination was used to identify HRCT parenchymal and vascular results which correlated with the results of the lung function tests. HRCT variables examined in the preceding bivariate analyses were entered as initial predictors, unless predictors were multi-collinear. All regression models were built in the sample size n=35. All final models satisfied the assumptions of multiple linear regression as determined by assessment of homoscedasticity, no multicollinearity between predictors and normal distribution of errors. In the longitudinal cohort, exploratory models were generated to test whether baseline vascular markers predicted subsequent deterioration of parenchymal disease and progression of lung function abnormalities. Logistic regression was used to assess the effect of baseline...
segmental A/B ratio and CSA<5mm on the deterioration in the overall CT appearance (‘Gestalt’ change score) and linear mixed model analysis (LMM) to predict individual decline in lung function results.

**Haematological data**

Haemoglobin, lactate dehydrogenase (LDH), bilirubin levels and reticulocyte counts were obtained from routine blood tests taken within one month of testing when patients were clinically stable.

Thirty-five patients with a median age of 43 (range 17-73) years were assessed. Twenty of the 35 patients (median age at initial assessment 38, range 17 – 66 years) had been assessed at a median of 6.6 (range 5.5-6.7) years previously. Of the thirty-three patients who participated in the original study 20 were tested at follow-up: three had died, six were lost to follow-up three declined to participate in the follow-up study and one declined to undergo HRCT scanning and was excluded. The twenty patients who were tested at follow-up were included in the 2009-2013 cohort, together with fifteen new patients making a total of thirty-five patients.
