ABSTRACT

Background Observational studies suggest that obesity is associated with increased risk of asthma. However, it is unknown whether this could be explained by wheezing. We tested the hypothesis that high body mass index (BMI) observationally and genetically is associated with high risk of wheezing and asthma, and that the association between high BMI and asthma is explained by wheezing.

Methods We genotyped 85 437 individuals aged 20–100 years from the Copenhagen General Population Study for *FTO* (rs9939609), *MC4R* (rs17782313), *TMEM18* (rs6548238) *GNPDA2* (rs10938397) and *BDNF* (rs10767664); 14 500 individuals experienced wheezing and 5406 had asthma. Wheezing was self-reported, and asthma was ascertained through self-report, hospital contacts with asthma, and/or receiving medication for asthma. BMI was calculated as measured weight divided by measured height squared (kg/m^2).

Results In observational analyses versus BMI of 18.5–22.4 kg/m^2 , ORs for wheezing were 1.23 (95% CI 1.00 to 1.52) for BMI <18.5 kg/m^2 , 1.17 (1.10 to 1.25) for 22.5–24.9 kg/m^2 , 1.44 (1.35 to 1.54) for 25–27.4 kg/m^2 , 1.86 (1.73 to 1.99) for 27.5–29.9 kg/m^2 , 2.48 (2.31 to 2.66) for 30–34.9 kg/m^2 , 3.86 (3.48 to 4.28) for 35–39.9 kg/m^2 and 6.05 (5.12 to 7.14) for BMI $\geq 40 \text{ kg/m}^2$. Corresponding ORs for asthma were 1.28 (0.95 to 1.74), 1.07 (0.97 to 1.17), 1.14 (1.04 to 1.25), 1.32 (1.20 to 1.46), 1.39 (1.25 to 1.54), 1.54 (1.31 to 1.81) and 1.99 (1.55 to 2.56), respectively. Compared with BMI allele score 0–4, scores 5, 6 and 7–10 were associated with 0.22, 0.51 and 0.76 kg/m^2 higher BMI, respectively. Genetically determined ORs per unit higher BMI were 1.22 (1.15 to 1.31) for wheezing, 1.18 (1.10 to 1.27) for wheezing without asthma, 1.08 (0.98 to 1.19) for asthma, and 0.85 (0.73 to 0.99) for asthma without wheezing. Corresponding observational ORs were 1.09 (1.09 to 1.10), 1.09 (1.08 to 1.09), 1.03 (1.03 to 1.04) and 0.99 (0.98 to 1.00), respectively.

Conclusions High BMI was associated with high risk of wheezing without asthma, but not with high risk of asthma without wheezing.

INTRODUCTION

Observational studies suggest that obesity is associated with increased risk of asthma,^{1–13} although there have been contradictory findings.^{3 14–16} Importantly, asthma can lead to physical inactivity

Key messages

What is the key question?

- Is high body mass index (BMI) observationally and genetically associated with asthma and wheezing, and is the association between high BMI and asthma explained by wheezing.

What is the bottom line?

- High BMI is associated with high risk of wheezing without asthma, but not with high risk of asthma without wheezing. In the future, doctors should be hesitant to prescribe anti-inflammatory asthma medication to obese individuals only because they wheeze.

Why read on?

- This is the first study to assess obesity as a potential causal risk factor in the development of asthma and wheezing using genetics.

which may lead to weight gain. Furthermore, obese individuals often wheeze,^{10 17} which could bias the association with asthma as wheezing also is a cardinal symptom of asthma. Thus, it is uncertain whether obesity causes asthma or whether the association is due to reverse causation and/or confounding.

Although randomised, double-blind, placebo-controlled clinical trials often are considered the gold standard in establishing causal relationships, some exposures like tobacco smoking, alcohol intake and obesity would be unethical or impractical to study in such a study design. Another limitation of randomised clinical trials includes, if there exists a long lead time between the exposure and development of disease, for example, obesity as a risk factor in development of asthma, as such studies would require unattainable economical resources. An alternative approach not prone to reverse causation and largely free of confounding is that of Mendelian randomisation, using genetic variants as proxies of modifiable exposures.¹⁸ Thus, genetic variants that specifically associate with lifelong high body mass index (BMI) provide an ideal design to assess consequences of obesity, independent of other risk factors.¹⁹ We here use genetic variation in *FTO* (rs9939609), *MC4R*

(rs17782313), *TMEM18* (rs6548238), *GNPDA2* (rs10938397) and *BDNF* (rs10767664), known to have the largest effect on BMI,²⁰ to assess obesity as a potential causal risk factor in the development of asthma.

We tested the hypothesis that high BMI observationally and genetically is associated with wheezing and asthma, and that the association between high BMI and asthma is explained by wheezing. For this purpose, we used the Copenhagen General Population Study (CGPS) with 85 437 individuals, of which 14 500 experienced wheezing and 5406 had asthma. First, we investigated whether BMI was associated with wheezing and asthma (step 1, figure 1). Second and third, we investigated whether the genetic variants were associated with BMI and with wheezing and asthma (steps 2 and 3, figure 1). Finally, we investigated whether the genetic variants were associated with wheezing and asthma consistent with their association with high BMI using instrumental variable analyses (step 4, figure 1).

METHODS

Participants

We included participants from CGPS, initiated in 2003 with ongoing enrolment.²¹ Individuals aged 20–100 years were randomly selected from the national Danish Civil Registration System to reflect the adult, white Danish population. All participants completed a comprehensive questionnaire, underwent a physical examination, and gave blood for biochemical and genetic analyses. Questionnaires were reviewed at the day of attendance by an investigator. At the time of genotyping, we had 85 437 individuals available. All participants were white and of Danish descent as recorded in the national Danish Civil Registration System. The study was conducted according to the Declaration of Helsinki.

Body mass index

Weight (kg) and height (m) were measured at the day of attendance by an investigator with one decimal, blinded to information on wheezing, asthma and genotype. BMI was calculated as weight divided by height squared (kg/m^2), and categorised similar to WHO: $<18.5 \text{ kg/m}^2$, $18.5\text{--}22.4 \text{ kg/m}^2$, $22.5\text{--}24.9 \text{ kg/m}^2$, $25\text{--}27.4 \text{ kg/m}^2$, $27.5\text{--}29.9 \text{ kg/m}^2$, $30\text{--}34.9 \text{ kg/m}^2$,

$35\text{--}39.9 \text{ kg/m}^2$ and $\geq 40 \text{ kg/m}^2$.²² BMI of $18.5\text{--}22.4 \text{ kg/m}^2$ was chosen as reference in the statistical analyses; obese individuals were those with BMI $\geq 30 \text{ kg/m}^2$.

Genotyping

Genotyping was conducted blind to information on BMI, wheezing and asthma. The ABI PRISM 7900HT Sequence Detection System (Applied Biosystems) was used to genotype *FTO* (rs9939609), *MC4R* (rs17782313), *TMEM18* (rs6548238), *GNPDA2* (rs10938397) and *BDNF* (rs10767664) with TaqMan assays; we chose the genetic polymorphisms known to have the largest effect on BMI.²⁰ Genotyping was verified by DNA sequencing. As we performed reruns twice, call rates were above 99.8%.

An aggregate instrument for BMI was created by constructing a score of 0–10 based on the number of alleles associated with high BMI across the five genotypes, as done previously.²¹ Allele score was categorised into 0–4 alleles ($n=23\,937$), 5 alleles ($n=23\,351$), 6 alleles ($n=21\,338$) and 7–10 alleles ($n=16\,811$), to achieve a large number of individuals in the groups and thus high statistical power.

Potential confounders

Information on potential confounders was acquired from the questionnaires and reviewed at the day of attendance by an investigator. Familial predisposition for asthma was defined as at least one first degree relative (father, mother and/or sibling) with asthma. Smoking status was categorised as never, former or current smokers. Cumulative tobacco consumption was defined as tobacco consumed through smoking and measured in pack years based on information on duration of tobacco smoking and current amount of tobacco consumed. Education was based on years attending school and categorised as <10 years, $10\text{--}12$ years and ≥ 13 years. Annual household income was reported as $<\text{Danish kroner (Kr)}200\,000$, $\text{Kr}200\,000\text{--}400\,000$, $\text{Kr}400\,000\text{--}600\,000$, $\text{Kr}600\,000\text{--}800\,000$ and $\geq \text{Kr}800\,000$. Degree of physical activity in leisure time was reported as none or light activity $<2 \text{ h/week}$, light activity $2\text{--}4 \text{ h/week}$, light activity $>4 \text{ h}$ or heavy activity $2\text{--}4 \text{ h/week}$, and heavy activity $>4 \text{ h}$ or regular exercises per week. Degree of physical activity during work was reported as sitting, sitting/standing/sometimes walking, walking/sometimes lifting, hard body work and retired/unemployed. Dietary intakes, including fast food, fruits and vegetables, were reported as number of intakes per day or week.

Outcomes and measures

Wheezing was defined as an affirmative response to the question: ‘Do you occasionally have whistling or wheezing while breathing?’ acquired from the questionnaire and reviewed at the day of attendance by an investigator.

Asthma was defined in four different ways: (1) Self-reported asthma: if participants responded affirmative to the question: ‘Do you have asthma?’ acquired from the questionnaire and reviewed at the day of attendance by an investigator; (2) Hospital contacts with asthma: if participants had an official doctor diagnosis of asthma, inpatient or outpatient (ICD8: 493 and ICD10: J45-J46) from 1977 until the day of attendance; (3) Receiving medication for asthma: if participants were never-smokers and responded affirmative to the question: ‘Do you take medication for asthma/bronchitis (including sprays/dry powders)?’ acquired from the questionnaire and reviewed at the day of attendance by an investigator; and (4) Any asthma: if participants were positive for one or more of the above definitions of asthma. Any participant who had hospital contacts with COPD (ICD8: 491-492 and ICD10: J41-J44) from 1977 until

Figure 1 Mendelian randomisation design in four steps. (1) Observational analyses suggest an association between BMI (kg/m^2) and wheezing and asthma with uncertainty regarding the direction of causation and limited information on possible confounders; (2) The association of BMI allele score with BMI; (3) The association of the BMI allele score with wheezing and asthma; (4) Determining if BMI is potentially causally related to wheezing and asthma by using BMI allele score as an instrumental variable. BMI, body mass index.

the day of attendance was excluded as an asthma case. Information regarding hospital contacts was obtained from the national Danish Patient Registry, covering all public and private Danish hospitals from 1977 until April 2013; we did not lose track of a single person during this period.

Statistical analyses

Deviation from the Hardy-Weinberg equilibrium with χ^2 tests was investigated to assess the frequency of allele distribution across the five genotypes; deviation may suggest genotyping or population sampling errors. We included age, sex, familial predisposition for asthma, smoking status, cumulative tobacco consumption, education, annual household income, physical activity in leisure time and during work, and dietary intakes, including fast food, fruits and vegetables, as potential confounders in observational analyses, as these may associate with BMI, wheezing and/or asthma. Age at the day of attendance of the participants was used in the statistical analyses. Some participants lacked information on some of these covariates, and we, therefore, performed multivariate imputation using chained equations to fill out the missing values (see online supplementary table S1); however, without imputation results were similar, that is, after excluding individuals with missing values. Cuzick's non-parametrical trend test was used to assess trend across BMI categories and allele scores. Comparison of participants with and without wheezing or asthma was determined using Wilcoxon's non-parametrical rank-sum test for continuous data and Pearson's χ^2 test for categorical data.

Association of observational BMI and genetic risk score for BMI (allele score) with wheezing and asthma was investigated using logistic regression (steps 1 and 3, figure 1). Association of allele score with BMI was estimated using multiple linear regressions with age and sex as covariates (step 2, figure 1). Finally, we investigated whether genetic high BMI was associated with wheezing and asthma by using the unweighted allele score in instrumental variable analyses, using the control function estimator in two stages (step 4, figure 1).^{19 23} For the control function estimator, we used the predicted values and residuals from the first-stage linear regression as variables in the second-stage logistic regression to investigate the association with wheezing and asthma. SEs were estimated using sandwich estimators. We used a generalised Hausman specification test to compare the instrumental variable analysis estimates with the observational estimates. The null hypothesis is that the observational estimator is an efficient and consistent estimator of the true parameters. If this is the case, there should be no systematic difference between the two estimators. We evaluated the strength of the instrumental variable by examining the F-statistic from the first-stage regression: $F > 10$ indicates sufficient strength to ensure statistical reliability of the instrumental variable estimates.¹⁹ The Wald test was used to assess interaction of BMI and sex on risk of wheezing and asthma, as sex differences have been suggested.^{1 3}

All statistical analyses were performed using STATA/SE V.13.0 for Windows (StataCorp, College Station, Texas, USA).

RESULTS

Among 85 437 individuals from CGPS, all of whom had all information available including genotypes, 14 500 experienced wheezing (17%) and 5406 had asthma (6%); asthma was defined as self-reported asthma, hospital contacts with asthma and/or receiving medication for asthma (see online supplementary figure S1). BMI, wheezing and asthma were associated with almost all of the potential confounders (see table 1 and online supplementary table S2). However, BMI allele score was not

associated with measured potential confounders (see table 1 and online supplementary table S3). Thus, BMI allele score can be used as a proxy for obesity and the association of obesity with wheezing and asthma can be studied largely free of confounding and without reverse causation as genotypes are present at birth. All genotypes were in Hardy-Weinberg equilibrium. Although individuals had a higher age on average, no differences could be observed according to the BMI allele score (table 1 and online supplementary table S3).

BMI and risk of wheezing and asthma: observational estimates

High BMI compared with BMI of 18.5–22.4 kg/m² was associated with high risk of wheezing and asthma, including self-reported asthma, hospital contacts with asthma, receiving medication for asthma and any asthma, in a dose-dependent manner when adjusting for potential confounders (see figure 2 and online supplementary figures S2 and S3). The ORs for wheezing were 1.23 (95% CI 1.00 to 1.52) for BMI <18.5 kg/m², 1.17 (1.10 to 1.25) for 22.5–24.9 kg/m², 1.44 (1.35 to 1.54) for 25–27.4 kg/m², 1.86 (1.73 to 1.99) for 27.5–29.9 kg/m², 2.48 (2.31 to 2.66) for 30–34.9 kg/m², 3.86 (3.48 to 4.28) for 35–39.9 kg/m² and 6.05 (5.12 to 7.14) for BMI ≥40 kg/m² (p for trend <1×10⁻³⁰⁰). Corresponding ORs for any asthma were 1.28 (0.95 to 1.74), 1.07 (0.97 to 1.17), 1.14 (1.04 to 1.25), 1.32 (1.20 to 1.46), 1.39 (1.25 to 1.54), 1.54 (1.31 to 1.81) and 1.99 (1.55 to 2.56) (p for trend=8×10⁻²⁰), respectively. High BMI was also associated with high risk of wheezing without asthma, but not with asthma without wheezing (figure 2). Corresponding ORs for wheezing without any asthma were 1.19 (0.94 to 1.50), 1.15 (1.07 to 1.24), 1.40 (1.30 to 1.51), 1.83 (1.70 to 1.98), 2.49 (2.30 to 2.69), 3.77 (3.37 to 4.22) and 5.77 (4.85 to 6.87) (p for trend=2×10⁻²⁵⁵), and for any asthma without wheezing 1.22 (0.80 to 1.86), 0.94 (0.83 to 1.07), 0.87 (0.76 to 0.99), 1.00 (0.87 to 1.16), 0.93 (0.79 to 1.08), 0.64 (0.47 to 0.88) and 0.90 (0.56 to 1.44) (p for trend=0.15), respectively. There was no evidence of sex difference in risk of wheezing as a function of BMI (p for interaction=0.99); however, the association of BMI with any asthma was driven by women and did not exist for men (p for interaction=0.001) (see online supplementary figure S4).

BMI allele score and BMI

Compared with BMI allele score 0–4, allele score 5 was associated with 0.22 kg/m² (95% CI 0.15 to 0.30) higher BMI (0.9% higher), allele score 6 with 0.51 kg/m² (0.43 to 0.58) higher BMI (1.9% higher) and allele score 7–10 was associated with 0.76 kg/m² (0.68 to 0.84) higher BMI (2.9% higher) (figure 3). The genetic variants explained 0.43% of the variation in BMI. The individual genotypes (*FTO*, *MC4R*, *TMEM18*, *GNPDA2* and *BDNF*) were each associated with higher BMI (see online supplementary figure S5).

BMI allele score and risk of wheezing and asthma: genetic estimates

High BMI allele score compared with BMI allele score of 0–4 was associated with high risk of wheezing in a dose-dependent manner, but not with asthma, including self-reported asthma, hospital contacts with asthma, receiving medication for asthma and any asthma (see figure 3 and online supplementary figure S6). Compared with allele score 0–4, ORs for wheezing and for wheezing without any asthma were 1.05 (95% CI 1.00 to 1.11) and 1.06 (1.00 to 1.12) for allele score 5, 1.10 (1.04 to 1.15) and 1.07 (1.01 to 1.13) for allele score 6, and 1.18 (1.12 to

Table 1 Characteristics of participants in the Copenhagen General Population Study according to body mass index categories at examination

Data are summarised as median with the 25th and 75th centiles, or per cent.

*p Values were calculated using Cuzick's non-parametrical trend test across ordered groups.

†Only current and former smokers were included.

‡p Value non-significant when adjusted for number of individual trend analyses according to the Bonferroni method.

Figure 2 Association of BMI with wheezing and asthma. ORs were multivariable adjusted for age, sex, familial predisposition for asthma, smoking status, cumulative tobacco consumption, education, annual household income, physical activity in leisure time and during work, and dietary intakes, including fast food, fruits and vegetables. p Values for trend were across ordered groups excluding participants with BMI <18.5 kg/m². BMI, body mass index.

1.24) and 1.16 (1.09 to 1.23) for allele score 7–10 (p for trend 3×10^{-10} and 1×10^{-6}). Corresponding ORs for any asthma and for any asthma without wheezing were 1.02 (0.95 to 1.10) and 1.02 (0.91 to 1.14), 1.05 (0.97 to 1.13) and 0.92 (0.82 to 1.04), and 1.06 (0.97 to 1.15) and 0.90 (0.79 to 1.01) (p for trend 0.13 and 0.03). A similar pattern was observed for the individual genotypes (*FTO*, *MC4R*, *TMEM18*, *GNPDA2* and *BDNF*) (see online supplementary figure S5). There were no evidence of sex differences in risk of wheezing and asthma according to allele score (see online supplementary figure S7).

BMI and risk of wheezing and asthma: observational versus genetic estimates

Genetically determined high BMI was associated with high risk of wheezing, but not with high risk of asthma (figure 4). Genetically determined ORs per unit higher BMI were 1.22 (95% CI 1.15 to 1.31) for wheezing, 1.18 (1.10 to 1.27) for wheezing without asthma, 1.08 (0.98 to 1.19) for any asthma and 0.85 (0.73 to 0.99) for any asthma without wheezing.

Corresponding observational determined ORs per unit higher BMI were 1.09 (1.09 to 1.10), 1.09 (1.08 to 1.09), 1.03 (1.03 to 1.04) and 0.99 (0.98 to 1.00), respectively.

Sensitivity analyses

In analyses stratified according to smoking status, results were similar (compare figure 4 and online supplementary figure S8). However, the risk of self-reported asthma was slightly higher in ever-smokers compared with never-smokers (p for interaction=0.04). In analyses stratified according to age, results were also similar, perhaps with attenuated association in younger compared with older individuals (compare figure 4 and online supplementary figure S9). Investigating risk of hospital contacts with asthma prospectively, with and without wheezing at baseline, results were similar (see online supplementary figure S10). Adjusting observational analyses for BMI allele score gave similar results, and no interaction between BMI and BMI allele score was present (see online supplementary figure S11). Finally, observationally and genetically determined high BMI was

Figure 3 Association of BMI allele score with BMI and with wheezing and asthma. BMI allele score was created using the genotypes *FTO* (rs9939609), *MC4R* (rs17782313), *TMEM18* (rs6548238), *GNPDA2* (rs10938397) and *BDNF* (rs10767664). Association between BMI allele score and BMI was adjusted for age and sex. ORs were adjusted for age and sex. Number of individuals for the different outcomes differs slightly due to availability of data. BMI, body mass index; F, statistical strength of BMI allele score as an instrument for BMI; R², measure of explained variation in BMI by BMI allele score.

associated with high risk of having asthma and wheezing combined (compare [figure 4](#) and online supplementary figure S12).

DISCUSSION

Among 85 437 adults from the general population, we found that high BMI was associated with high risk of wheezing without asthma, but not with high risk of asthma without wheezing ([figure 5](#)). These are novel findings using novel techniques.

Mechanistically, the present findings possibly can be explained in a simple and straightforward manner: obesity causes reductions in lung and chest wall compliance (increased stiffness) by the presence of excess adipose tissue on the chest wall, on the abdomen, as well as intra-abdominally.²⁴ In other words, because of excess fat deposited on all borders of the lungs, it becomes very difficult for obese people to breathe normally, which results in airway compression leading to frequent

Figure 4 Association of genetic and observational determined BMI with wheezing and asthma. ORs from the observational estimates included only participants with BMI ≥18.5 kg/m², and were multivariable adjusted for age, sex, familial predisposition for asthma, smoking status, cumulative tobacco consumption, education, annual household income, physical activity in leisure time and during work, and dietary intakes, including fast food, fruits and vegetables. ORs for genetic analyses were obtained from the instrumental variable analyses. p Values for comparison were obtained with the Hausman specification test. BMI, body mass index.

Figure 5 Mendelian randomisation design in a DAG diagram including main results. (1) The association of BMI with wheezing without asthma and with asthma without wheezing could be influenced by confounding and/or reverse causation, limitations that conventional observational studies have; (2) However, by using the genetic variants, *FTO*, *MC4R*, *TMEM18*, *GNPDA2* and *BDNF*, that specifically are associated with lifelong high BMI, a Mendelian randomisation study can be conducted; (3) In a Mendelian randomisation study, the *FTO*, *MC4R*, *TMEM18*, *GNPDA2* and *BDNF* are used as proxies of BMI in an instrumental variable analysis, investigating the association with wheezing without asthma and with asthma without wheezing by avoiding confounding, as the genetic variants only can be associated through BMI following Mendelian inheritance, and reverse causation, as the genetic variants are present at birth. BMI, body mass index; DAG, direct acyclic graph; IV, instrumental variable.

episodes of wheezing.^{10 17} This symptom, however, need not necessarily be an expression of asthmatic airways inflammation.

Previous findings in support of our observations suggest that obesity is associated observationally with increased risk of asthma in some,^{1-7 9-13} but not in all studies.^{3 14-16} Importantly, previous studies did not explore whether the asthma association could be explained by wheezing, including a recent Mendelian randomisation study in children.²⁵ Also, intervention studies with weight loss were associated with reduced need for asthma medication and improvement of respiratory symptoms in obese individuals with asthma.⁸ However, although weight loss may be beneficial for obese individuals with asthma, this does not necessarily imply that obesity is a causal risk factor for asthma. Indeed, obesity has been shown not to be related to airflow limitation²⁶ and findings regarding airway hyper-responsiveness have been inconclusive,²⁷ both included in the diagnosis of asthma.²⁸ Overdiagnosis of asthma in adults is a well known problem.²⁹ Importantly, obese individuals seem more prone to be misdiagnosed with asthma compared with normal weight individuals.^{30 31} Thus, it is likely that overdiagnosis of asthma because of wheezing among obese individuals is an explanation for previous findings of an association between obesity and asthma, in line with findings in the present study. The fact that anti-inflammatory asthma treatment in obese individuals works poorly is also in keeping with the possibility of overdiagnosis of asthma in obesity.³² It is also puzzling that the observational association between BMI and asthma were driven by women and did not exist for men; a plausible explanation may be that women seek their doctors more often as opposed to men, thereby, tend to be more often overdiagnosed with asthma. By contrast, the corresponding genetic association did not exist for either men or women.

Recently, in another Mendelian randomisation study, obesity was observed to be associated with childhood asthma.²⁵ However, in that study wheezing was included in the definition of asthma, and the study thus did not address whether asthma

could be misdiagnosed based on wheezing in obese children. Another explanation could be that asthma in childhood compared with in adulthood may be a different phenotype.

Potential limitations in Mendelian randomisation studies include population stratification, genetic pleiotropy and linkage disequilibrium.^{18 19} However, as we had an ethnically homogeneous population, the complicating effects of population stratification are likely to have been avoided. Although there seems to be genetic pleiotropy or linkage disequilibrium between genetic variants associated with obesity and asthma,³³ by using five different genetic variants, which are independently associated with high BMI via different pathways, genetic pleiotropy and linkage disequilibrium are likely to have been avoided, since results were similar when using allele score or the individual genotypes. However, we cannot exclude that the allele score or the individual genotypes are associated with unmeasured confounders. Another potential limitation of our study was that the diagnosis of asthma was not defined according to the presence of reversible or variable airflow limitation and/or airway hyper-responsiveness²⁸; however, this is not a feasible approach in large-scale population-based studies. Importantly, we used a definition of asthma which previously has been applied in numerous observational studies that also found an association between obesity and asthma. Furthermore, self-reported asthma has been evaluated rigorously before and displays high specificity and sensitivity,^{34 35} compared with airway hyper-responsiveness which only displays high specificity but low sensitivity.³⁶ Also, we included hospital contacts with asthma and receiving medication for asthma as additional asthma definitions, which showed similar associations with obesity as that observed for self-reported asthma. Although we had the opportunity to investigate different definitions of asthma, it is important to acknowledge that lack of power could be an explanation for not observing an association between obesity and asthma. However, the fact that we by using the same population using the same observational BMI and the same BMI allele score were able to find clear results for wheezing without asthma argue against this possibility. Lastly, we were unable to differentiate between mild and severe asthma. However, it could be argued that self-reported asthma would have a higher proportion of milder cases of asthma compared with receiving medication for asthma or having a hospital contact with asthma, and when these end points were analysed separately, the results were similar, suggesting that the findings apply to mild asthma and severe asthma.

Strengths of the present study include a large population sample with large number of individuals experiencing wheezing and many individuals with asthma. Another strength is an objective measurement of weight and height in contrast to some previous studies which used self-reported values.^{1 3 5 7 9-11 13} Finally, we did not lose track of even a single person from 1977 through April 2013.

In conclusion, high BMI was associated with high risk of wheezing without asthma, but not with high risk of asthma without wheezing. These are novel observations with the potential to change clinical practice: in the future, doctors should be hesitant to prescribe anti-inflammatory asthma medication to obese individuals only because they wheeze.
