ABSTRACT

Background Prior randomised trials have evaluated statins in patients with sepsis and acute respiratory distress syndrome (ARDS), but there has been no comprehensive evaluation of long-term effects, despite potential neuromuscular and mental health adverse effects of these drugs.

Aim To evaluate the effect of rosuvastatin versus placebo on survival, physical function and performance, and mental health outcomes in patients with sepsis-associated ARDS.

Methods Prospective follow-up evaluation of the ARDS Clinical Trials Network Statins for Acutely Injured Lungs from Sepsis trial of rosuvastatin versus placebo in 568 mechanically ventilated patients with sepsis-associated ARDS, with blinded 6-month outcome assessment performed in the 272 eligible survivors for age-adjusted and sex-adjusted 36-Item Short Form Health Survey (SF-36) physical function and mental health domains, and in 84 eligible survivors for the 6 min walk test, along with secondary outcomes evaluations of survival, and additional patient-reported and performance-based measures at 6-month and 12-month follow-up.

Results Over 1-year follow-up, there was no significant difference in cumulative survival in the rosuvastatin versus placebo groups (58% vs 61%; $p=0.377$), with survivors demonstrating substantial impairments in physical function and mental health. Rosuvastatin versus placebo had no effect (mean treatment effect (95% CI)) on SF-36 physical function (0 (−7 to 8), $p=0.939$) or mental health (−6 (−12 to 1) $p=0.085$) domains, 6 min walk distance (per cent predicted: 2 (−9 to 14), $p=0.679$) or the vast majority of secondary outcomes.

Conclusions Over 1-year follow-up, patients with sepsis-associated ARDS had high cumulative mortality, with survivors commonly experiencing impairments in physical functioning and performance, and mental health. Randomisation to rosuvastatin had no effect on these outcomes.

Trial registration number NCT00979121 and NCT00719446.

INTRODUCTION

In sepsis-associated acute respiratory distress syndrome (ARDS), rosuvastatin versus placebo was

Key messages

What is the key question?

- Does rosuvastatin use in the intensive care unit affect long-term survival, and physical and mental health outcomes in patients with sepsis-associated acute respiratory distress syndrome (ARDS)?

What is the bottom line?

- Over 6-month and 12-month follow-up, there is no evidence from this study that randomisation to rosuvastatin had any effects on survival, physical functioning and performance and mental health outcomes.

Why read on?

- These patients with sepsis-associated ARDS had high cumulative mortality, with survivors commonly experiencing impairments in physical functioning and performance, mental health and quality of life, further highlighting the need for novel interventions to mitigate these impairments.

tested in a large, multicentre, randomised study, Statins for Acutely Injured Lungs from Sepsis (SAILS) trial. This trial, conducted by the NHLBI ARDS Clinical Trials Network (ARDSNet), reported no significant difference in short-term mortality and ventilator-free days.¹ This study exemplifies the great interest in evaluating 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) in patients with sepsis, ARDS and other critical illness, with at least 10 additional randomised trials conducted.^{2–5} Despite such interest, there has been no comprehensive evaluation of potential benefits and risks of statins beyond 90-day follow-up.

Importantly, in addition to their hypothesised beneficial pleiotropic effects, statins have known toxicity to liver and skeletal muscle, even when administered for a short time.⁶ In the SAILS trial,

patients randomised to rosuvastatin had significantly fewer hepatic and renal failure-free days, and higher serum levels of aspartate aminotransferase, with some having concurrent elevations of creatine kinase and alanine aminotransferase indicating potential muscle and/or liver toxicity.¹ Moreover, in an ancillary study, a subgroup of SAILS patients underwent blinded electromyography and nerve conduction studies, finding increased prevalence of neuromyopathy in rosuvastatin versus placebo group at study day 7 (63% vs 33%, $p=0.05$).⁷ Any rosuvastatin-associated neuromuscular injury may exacerbate other forms of muscle injury and wasting commonly occurring early during critical illness.⁸ Hence, assessing for long-term neuromuscular and related physical effects of statin administration in the intensive care unit (ICU) is important.¹

In addition to these physical effects, statins have known adverse mental health effects, including depression, nightmares and paranoia that may be more common in patients with other mental health impairments.⁹ Notably, patients with ARDS have a high prevalence and co-occurrence of mental health impairments before, during and after their ICU stay,^{10–11} including incident post-traumatic stress disorder (PTSD) symptoms associated with nightmares and flashbacks to frightening ICU memories.¹² Such post-ICU mental health impairments might be exacerbated if exposure to statins caused nightmares or paranoia in the ICU.

Finally, prior randomised trials in sepsis and ARDS have demonstrated that both non-significant and significant differences in short-term mortality may markedly change over 6-month to 12-month follow-up,^{13–14} underscoring the need for monitoring of survival beyond 60-day to 90-day follow-up.¹⁵ Such monitoring is especially important since organ failure¹⁶ and neuromuscular dysfunction¹⁷ in the ICU are associated with mortality up to 1-year later and these factors differed between treatment groups in SAILS, with SAILS demonstrating a non-significant increase in in-patient mortality up to 60 days after randomisation (rosuvastatin vs placebo: 28.5% vs 24.9%, $p=0.21$).¹

Given above rationale, via the ARDSNet Long-Term Outcomes Study (ALTOS), we conducted a prospective longitudinal evaluation of SAILS patients' outcomes over 6-month and 12-month follow-up to evaluate the effect of rosuvastatin versus placebo on physical function and performance, mental health and survival.

METHODS

Consenting patients from 35 of 37 hospitals participating in SAILS were eligible for phone-based, patient-reported outcomes assessments as part of this prospective, longitudinal follow-up study. At 23 of these hospitals, due to funding issues, recruitment stopped for ≥ 7 months (December 2011 to July 2012). In addition to phone-based assessments, patients from 12 of the 35 hospitals were also recruited for in-person physical performance assessments. Patient follow-up occurred from 2010 to late 2014. Each participating site's institutional review boards approved this study. Informed consent was obtained from each patient or his/her proxy (if patient was incapable of consent).

Patients

SAILS eligibility criteria and study intervention have been reported previously, and summarised briefly herein.¹ Patients were randomised (stratified by hospital site) to receive either enteral rosuvastatin or placebo until the earliest of 3 days after ICU discharge, study day 28 or death. These patients were managed with fluid conservative and lung-protective ventilation

protocols, with similar average fluid balances and tidal volumes for both treatment groups.¹ SAILS was stopped for futility after 745 of 1000 patients were enrolled, with no significant differences in short-term mortality, ventilator-free days and ICU-free days. In recruiting SAILS participants for follow-up via the ALTOS study, the following additional exclusion criteria were applied: <18 years old, non-English speaking, homeless or cognitively impaired, evaluated based on patients' status prior to hospitalisation using medical record review and/or interview with the patient and/or proxy. The first 75 SAILS patients enrolled into this follow-up study were co-enrolled in the ARDSNet EDEN (Early vs. Delayed Enteral Nutrition) trial, which evaluated initial trophic versus full enteral feeding up to 6 days after ARDS, and demonstrated no significant differences in short-term outcomes or 6-month and 12-month physical function and performance, mental health and survival.^{18–20}

Study procedures

At 6-month and 12-month follow-up, research personnel, blinded to treatment allocation, completed study assessments via phone (details in 'Patient-reported outcomes—physical function and mental health symptoms' section). Loss to follow-up was minimised by using established cohort retention methodology.²¹ If unable to complete the study assessment via phone, surveys were completed by mail (6% of all assessments at the 6-month primary outcome time-point) and/or by designated proxies (only for two secondary outcome measures, the Functional Performance Inventory (FPI)-Short Form and Employment status, representing 12% of these 6-month assessments).

For patients undergoing in-person physical performance assessments at 6-month and 12-month follow-up, research staff, blinded to treatment allocation, collected baseline comorbidity status (using the Functional Comorbidity Index²²) from the medical record and completed testing (details in 'Performance-based physical assessments' section).

Primary and secondary outcomes

Patient-reported outcomes—physical function and mental health symptoms

The primary patient-reported outcomes were the age-adjusted and sex-adjusted physical function and mental health domain scores of the Medical Outcomes Study Short Form 36 V.2 (SF-36) instrument²³ (range: 0–100; higher score is better) at 6-month follow-up, with 12-month scores as a secondary outcome.

Other secondary outcomes, at 6-month and 12-month follow-up, included: SF-36 physical and mental health summary normalised scores (mean=50; SD=10; higher score is better); the EQ-5D-3L²⁴ generic quality of life instrument utility score²⁵ (range: –0.11 to 1.0; higher score is better) and visual analogue scale score (range: 0–100; higher score is better); the FPI-Short Form²⁶ overall functional activity score and subscale scores for physical exercise, maintaining household and body care (for each, range: 0–3; higher score is better); Hospital Anxiety and Depression Scale (HADS)²⁷ subscale scores for anxiety and depression symptoms (for each, range: 0–21; lower score is better, with scores ≥ 8 indicating substantial symptoms); Impact of Events Scale-Revised for PTSD symptoms (range: 0–4; lower score is better, with scores ≥ 1.6 indicating substantial symptoms²⁸) and employment status (full-time or part-time work vs unemployed).¹⁸

Performance-based physical assessments

For the subset of patients undergoing physical performance assessments, the primary outcome was the 6-month, 6 min walk

test, evaluated as a per cent of the predicted value,²⁹ with 12-month values as a secondary outcome.

Other secondary physical performance outcomes, at 6-month and 12-month follow-up, included: 4 m gait speed (m/s);³⁰ manual muscle testing using the Medical Research Council sum-score (range: 0–60; <48 indicating 'ICU-acquired weakness'³¹); per cent of predicted value for hand grip strength,³² maximal inspiratory pressure,³³ FEV₁, and FVC;³⁴ body mass index (BMI) and per cent fat and muscle areas based on upper arm anthropometric assessment.³⁵

Statistical analyses

Baseline patient and intensive care variables were compared between the two treatment groups using counts and percentages, or means and SDs. The Kaplan–Meier method was used to estimate the cumulative proportion of survivors throughout the follow-up period separately for rosuvastatin and placebo groups, and compared using the log-rank test. Patients ineligible for follow-up were censored at hospital discharge and those with unknown mortality at 12 months censored at 6 months. At each follow-up, the mean and the odds of the continuous and binary outcomes, respectively, were estimated using linear and logistic random intercept regression models, including main effect of follow-up time-point (12 vs 6 months). The patient-reported primary outcomes (ie, 6-month SF-36 physical function and mental health domains) were compared across treatment groups using linear regression with the main effect of treatment, adjusting for sex and age (using a linear spline with a knot at 50 years

old due to a non-linear association of age with outcomes).³⁶ The physical performance primary outcome (ie, 6 min walk test per cent predicted score at 6-month assessment) was compared across treatment groups using linear regression with the main effect of treatment only.

A series of sensitivity analyses for the primary outcomes were completed. First, patients who consented, but died prior to 6 months were included with their outcome value set to the worst possible value. In addition, the Wilcoxon U statistic was computed after ranking the patients by their outcome score with death assigned the worst rank.³⁷ Second, the linear regression models were expanded to also adjust for ARDS risk factor (pneumonia vs other), Acute Physiology and Chronic Health Evaluation III (APACHE III) score, Alcohol Use Disorders Identification Test score in the patient-reported outcome regression model and for BMI, and Functional Comorbidity Index, APACHE III and baseline SF-36 PF domain scores (obtained retrospectively) for the physical performance outcomes. Third, the regression models were extended to include a statistical interaction term to explore possible effect modification of the SAILS and EDEN randomised assignments.

Analysis of secondary outcomes compared the mean or the odds for continuous and binary outcomes across the two treatment groups, separately at 6-month and 12-month follow-up, using linear or logistic random intercept regression models, respectively. The models included main effects of treatment group and follow-up time-point (12 vs 6 months) and their interaction. Age and sex were included in the models using

Figure 1 Enrolment and follow-up. ^aLess than the 745 patient sample size of the SAILS trial due to two sites not participating in this study and a temporary cessation of recruitment into this study. ^bEight eligible patients were missed due to temporary cessation of recruitment for ≥ 7 months for the majority of study sites. ^cFour of these five patients were alive at 12 months and one was censored for survival analysis. ^dTwelve patients were alive at 12 months. ALTOS, ARDSNet Long-Term Outcomes Study; SAILS, Statins for Acutely Injured Lungs from Sepsis.

SF-36 data. For sensitivity analysis, these secondary analyses were repeated including patients who consented, but died prior to the 6-month or 12-month follow-up, as previously described.

Several a priori subgroup analyses of the treatment effect were performed for all primary and secondary outcomes. The following subgroups were evaluated: age (continuous), APACHE III (continuous), baseline BMI (<30, ≥30), ARDS subgroup (PaO₂/FiO₂ ≤200 vs >200), shock at baseline (present vs absent) and statin use immediately prior to hospitalisation (yes vs no). For physical performance outcomes, additional subgroups included: sex, an indicator for the patient being in the ICU on study day 7 (reflecting more prolonged exposure to rosuvastatin under the SAILS protocol), Functional Comorbidity Index, baseline FPI survey score (retrospectively obtained) and baseline SF-36 PF domain score (normed; retrospectively obtained). The subgroup analyses were fit using the same, previously described, random intercept regression models, but

included the subgroup variable and the following interactions: (1) treatment group and subgroup variable, (2) time and subgroup variable and (3) time, subgroup variable and treatment group. A post-hoc analysis compared the primary outcomes between patients in highest quartile of decrease in C reactive protein (CRP) levels and those in the lowest quartile. Additionally, we also completed a single post-hoc sensitivity analyses to explore clustering effects by hospital site by adding a random intercept for hospital to the statistical models.

The parent trial for this study (SAILS trial) was designed with 92% power to detect a 9% absolute difference in mortality comparing rosuvastatin versus a placebo control (18% vs 27%, respectively), with a sample size of 1000 patients. However, the trial was stopped for futility after enrolling 745 patients. For this prospective, longitudinal follow-up study of the SAILS trial, it was hypothesised that rosuvastatin would be harmful relative to placebo; however, there was no a priori effect size

†Details of test scoring: SF-36 physical function and mental health domains (range: 0–100; higher score is better); SF-36 physical and mental health summary normalised scores (mean=50; SD=10; higher score is better); EQ-5D utility score (range: −0.11 to 1.0; higher score is better) and visual analogue scale score (range: 0–100; higher score is better); FPI-Short Form overall score and subscale scores (for each, range: 0–3; higher score is better); HADS subscale scores for anxiety and depression (for each, range: 0–21; lower score is better, with scores ≥8 indicating substantial symptoms); IES-R (range: 0–4; lower score is better, with scores ≥1.6 indicating substantial symptoms); manual muscle testing score (range: 0–60; higher score is better, with scores <48 indicating 'ICU-acquired weakness').

‡Calculations from linear or logistic regression models with random intercept for subject and an indicator for time (12-month vs 6-month follow-up). 'Difference' represents the estimated difference between 12 and 6 months in mean score for continuous measures or in proportion for binary measures.

§Employment at 6 and 12 months calculated for all patients regardless of reported baseline employment status.

BMI, body mass index; HADS, Hospital Anxiety and Depression Scale; ICU, intensive care unit; IES-R, Impact of Event Scale—Revised; Norm, mean population norm; SF-36, Medical Outcomes Study Short Form 36 V.2.

specification or power calculation conducted since the sample size was known to be dependent on the available patients at the participating sites during the eligible enrolment period.

Analyses were performed using SAS V.9.3 (SAS Institute, Cary, North Carolina, USA) using data from all eligible consenting survivors according to an a priori written statistical analysis plan, with missing data excluded given a low rate of missingness for the patient-reported primary outcomes. A two-sided $p < 0.05$ was considered significant.

RESULTS

The sites participating in this follow-up study recruited 568 patients, of which 293 (52%) were randomised to rosuvastatin. Of the 568 patient cohort, 154 (27%) died prior to discharge

from hospital or after discharge before consent for follow-up, and 142 (25%) met exclusion criteria, leaving 272 patients consented for follow-up (figure 1). These 272 patients had a mean (SD) age of 51 (15) years, 53% women, 88% living at home independently, 72% with PaO₂/FiO₂ ratio ≤200 and 39% with shock. The baseline characteristics of the rosuvastatin versus placebo groups were generally similar for this cohort and the entire SAILS cohort (N=745), overall ALTOS cohort (N=568) and the ALTOS subgroup enrolled for in-person physical assessments (N=84) (table 1 and online supplementary table S1).

Patient outcomes at 6 and 12 months for all patients

Over 12-month follow-up, the cumulative mortality rate for all 568 ALTOS participants was 41%. At 6-month and 12-month

Figure 2 Survival until 12 months after randomisation. This figure illustrates the proportion of patients surviving in the study over time for the 568 patients in the ARDSNet Long-Term Outcomes Study cohort, with those who were alive, but excluded from follow-up, censored at hospital discharge. One consenting patient was censored at the 6-month assessment due to loss to follow-up thereafter. Patients who were known to be alive, but missed their 12-month follow-up assessment, were censored at the expected date of their 12-month assessment. The cumulative 1-year survival rate for rosuvastatin versus placebo was 58% vs 61% ($p=0.377$).

follow-up, respectively, 238 and 237 survivors were eligible for follow-up, and 233 (98%) and 220 (93%) were assessed (figure 1). At 6-month follow-up, patients had significantly lower SF-36 physical and mental health domain scores compared with age-matched and sex-matched population norms (table 2). Functional activities, measured by the FPI, had a mean (SD) overall score of 1.9 (0.7), signifying 'some difficulty' with activities (table 2). At 6 months, mental health symptoms were also common, with 46%, 37% and 25% of patients having substantial symptoms of anxiety, depression and PTSD, respectively. Between 6-month and 12-month follow-up, there was little evidence of clinically and statistically significant improvements in these outcomes (table 2). In terms of employment, 19% and 24% of survivors were working at 6 and 12 months; and of those employed prior to hospitalisation for ARDS, 43% and 46% had returned to work at 6 and 12 months, respectively.

In the subset of patients completing the performance-based physical assessments (see table 2 and online supplementary figure 1), the mean (SD) per cent predicted value for the 6 min walk test, at 6 and 12 months, was 65% (24%) and 71% (23%), respectively ($p=0.001$ for increase over time). ICU-acquired weakness (manual muscle test score <48 out of 60) occurred in three (4%) and one (2%) patient at 6 and 12 months, respectively. Mean (SD) values for other physical assessments, evaluated as per cent predicted values at 6 and 12 months, were: hand grip strength (83% (29%) and 91% (32%), $p=0.001$ for increase over time) and maximal inspiratory pressure (85% (32%) and 98% (32%), $p<0.001$).

Rosuvastatin versus placebo

Over 12-month follow-up, there was no significant difference in survival across the treatment groups, with an estimated proportion of patients surviving to 12 months for rosuvastatin versus placebo of 58% vs 61% ($p=0.377$; figure 2). At 6-month follow-up, there also was no significant difference in mean (SD)

SF-36 physical function domain score for rosuvastatin versus placebo (51 (32) vs 47 (32)), with an age-adjusted and sex-adjusted mean difference (95% CI) of 0 (−7 to 8); $p=0.939$). Similarly, there was no difference in the mean (SD) SF-36 mental health domain score: 38 (12) vs 36 (12) (adjusted difference: −6 (−12 to 1), $p=0.496$), or in any other patient-reported outcome (table 3 and figure 3).

For the performance-based physical assessments, at 6-month follow-up, there was no significant difference in the primary outcome of mean (SD) 6 min walk test per cent predicted value for rosuvastatin versus placebo (65% (22%) vs 64% (25%)), with a mean difference (95% CI) of 2% (−9% to 14%); $p=0.679$). There also was no significant difference in the other physical performance tests evaluated (table 3 and figure 3).

The preceding results for patient-reported outcomes and physical assessments at 6 months were similar with 12-month assessments and with all sensitivity analyses (as described in the Methods section), including no significant effect of statins on patient recovery between 6-month and 12-month follow-up. Moreover, across the a priori subgroup analyses (as described in the Methods section), there were no significant differences, except as reported herein. First, at 6-month and 12-month follow-up, in patients with BMI <30 kg/m², rosuvastatin patients had a greater odds of substantial symptoms of anxiety (HADS anxiety score ≥ 8) compared with placebo, but no significant difference in anxiety symptoms modelled as a continuous outcome. Second, at 6-month and 12-month follow-up, in patients with PaO₂/FiO₂ ≤ 200 , the rosuvastatin group had a greater odds of substantial symptoms of depression (HADS depression score ≥ 8), but no significant difference in depression symptoms modelled as a continuous outcome. Third, at 12-month follow-up (only), in patients with a greater difficulty in performing activities at baseline (ie, lower FPI score prior to ARDS), the rosuvastatin group had lower mean grip strength. Fourth, at both 6 and 12 months, in patients with higher

‡Calculated from linear or logistic regression models with random intercept and an indicator for treatment (rosuvastatin vs placebo), time (12 vs 6 months follow-up) and the interaction of treatment group and time. The treatment effect represents the mean difference in score for continuous measures and the odds ratio for binary measures.

§Adjusted for age and sex within the linear regression model described above.

BMI, body mass index; FPI, Functional Performance Inventory; HADS, Hospital Anxiety and Depression Scale; ICU, intensive care unit; IES-R, Impact of Event Scale—Revised; Norm, mean population norm; SF-36, Medical Outcomes Study Short Form 36 V.2.

number of comorbid conditions (ie, higher Functional Comorbidity Index score prior to ARDS), the rosuvastatin group had higher mean BMI and arm fat percentage than the control group. Lastly, there was no benefit of rosuvastatin versus placebo in the primary outcomes when comparing those in highest quartile decrease of CRP versus those in the lowest quartile. Post-hoc sensitivity analysis accounting for clustering by study hospital demonstrated no qualitative change in results from the primary analysis.

DISCUSSION

In this 12-month, prospective follow-up study of 568 patients with sepsis-associated ARDS participating in the SAILS trial of

rosuvastatin versus placebo, cumulative mortality was 41%, with the 272 survivors' physical functioning and performance and mental health status being below predicted values. Despite the known associations of statin use with neuromuscular and mental health side effects, in this randomised trial, randomisation to rosuvastatin did not affect survival, physical functioning and performance, or mental health outcomes at 6 and 12 months after ARDS.

Comparison with other studies

The physical and mental health impairments reported in this study are similar to a prior national cohort of 563 ARDS survivors from ARDSNet's EDEN trial.^{18 19} These impairments also were similar to prior smaller studies of ARDS survivors.^{10 38 39}

Figure 3 Forest plot—patient-reported and performance-based physical outcomes. This figure illustrates the treatment effect for rosuvastatin versus placebo, presented as an effect size, with 95% CI, for the primary outcome (age-adjusted and sex-adjusted SF-36 physical function and mental health domains and 6 min walk test per cent predicted) and all secondary outcomes. Effect size was calculated as the treatment effect (table 3, difference in means or proportions) divided by the pooled SD from the rosuvastatin and placebo groups.^{49 50} HADS, Hospital Anxiety and Depression Scale; IES-R, Impact of Event Scale—Revised.

Within this study, patient-reported physical outcomes may appear discordant with performance-based outcomes, consistent with previous studies demonstrating a lack of strong correlation between patient-reported physical function and performance-based measures.⁴⁰ Therefore, there is need for continued investigation into interventions that may reduce post-ICU physical and mental health impairments experienced by the growing number of ICU survivors,⁴¹ and to consider use of both patient-reported and performance-based outcome measures.

This study found no negative or positive effects of rosuvastatin on physical function and performance or mental health outcomes at 6-month and 12-month follow-up. There are several possible explanations. First, these findings may be attributable to the relatively short duration of rosuvastatin exposure (median of 9 days) in SAILS.¹ Second, rosuvastatin may have had shorter-term effects that did not persist until the initial 6-month follow-up assessment in this study, given that statin-associated myopathy, behavioural problems and mood disorders may resolve within weeks to months after medication cessation.⁹ Lastly, rosuvastatin's hydrophilic structure may impede crossing the blood-brain barrier, potentially decreasing any adverse effects observed for other more lipophilic statins. For example, the majority of statin-associated behavioural and mood disorders have been reported with the lipophilic statins, simvastatin and atorvastatin.⁹

The lack of negative effects of rosuvastatin, a hydrophilic statin, at 6 and 12 months in this study have clinical implications. For example, coupled with lack of short-term harm in a trial of simvastatin, a lipophilic statin in patients with ARDS,⁴² this study helps provide further reassurance of the safety of continuing pre-existing statin therapy during ICU. This finding is important given that stopping statins may be associated with rebound in inflammatory markers and loss of cardiovascular-related protective effects.^{43 44}

Strengths and limitations

This study has several strengths, including being the first large-scale, randomised trial of statins in critical illness to assess

survival beyond 90 days, as well as to comprehensively assess key functional outcomes, such as physical and mental health status. However, there are potential limitations. First, the results may not be generalisable to all patients with ARDS since the SAILS trial enrolled a relatively young cohort of patients with sepsis-associated ARDS with less severe comorbidity due to enrolment screening. Second, outcomes may not be generalisable to the entire SAILS cohort since outcomes were measured only in a subset of patients, partly due to the competing risk of death.⁴⁵ However, the available cohort for follow-up has similar baseline characteristics as the full cohort, with similar follow-up exclusion rates and mortality rates between treatment groups. Also, sensitivity analyses specifically addressing the competing risk of mortality did not result in any material change in the results. Third, this study could not prospectively measure patients' baseline status in order to understand new impairments arising after critical illness. However, baseline characteristics were similar between groups after randomisation with 88% of patients independently living at home, with evidence of new or worsening impairments after ARDS supported by 57% of previously employed patients not working at 6 months, 25% of participants reporting substantial PTSD symptoms specifically attributable to their ICU stay and a threefold increase in the proportion of participants reporting at least 'much' difficulty with basic functional activities for the patient subset that completed physical performance assessments. Moreover, prior studies, with prospective baseline assessments, have clearly demonstrated the incidence of new impairments across physical and mental health after critical illness.^{46 47} Fourth, there were missed assessments during longitudinal follow-up that may introduce bias. However, rates of missed follow-up assessments were similar between the randomised groups, and were very low ($\leq 3\%$) for the patient-reported outcomes at the 6-month primary outcome time-point. Moreover, there was little evidence to support a difference between rosuvastatin versus placebo in the primary outcome measures evaluating both patient-reported physical function ($p=0.939$) and performance-based physical assessment

(0.679), suggesting that missing data would not materially change the conclusions made from this study. Finally, because the first outcome assessment occurred at 6 months after ARDS, we cannot rule out an undetected short-term effect of rosuvastatin on patients' physical or mental health outcomes. However, the focus of this study was specifically to evaluate for effects lasting beyond the short-term, as recommended by many professional and scientific organisations.^{41 48}

CONCLUSION

This prospective 12-month evaluation of 568 patients with sepsis-associated ARDS participating in the SAILS trial of rosuvastatin versus placebo demonstrated high cumulative mortality, with the 272 survivors commonly experiencing important impairments in physical functioning and performance and mental health status. Despite known side effects of statins on neuromuscular function and mental health, there was no evidence of harm or benefit of randomisation to rosuvastatin on survival, physical functioning and performance or mental health over 1-year follow-up.
