Inspiratory muscle training to enhance recovery from mechanical ventilation: a randomised trial

Bernie M Bissett,1,2,3 I Anne Leditschke,4,5,6 Teresa Neeman,7 Robert Boots,1,8 Jennifer Paratz1,8,9

ABSTRACT

Background In patients who have been mechanically ventilated, inspiratory muscles remain weak and fatigable following ventilatory weaning, which may contribute to dyspnoea and limited functional recovery. Inspiratory muscle training may improve inspiratory muscle strength and endurance following weaning, potentially improving dyspnoea and quality of life in this patient group.

Methods We conducted a randomised trial with assessor-blinding and intention-to-treat analysis. Following 48 hours of successful weaning, 70 participants (mechanically ventilated ≥7 days) were randomised to receive inspiratory muscle training once daily 5 days/week for 2 weeks in addition to usual care, or usual care (control). Primary endpoints were inspiratory muscle strength and fatigue resistance index (FRI) 2 weeks following enrolment. Secondary endpoints included dyspnoea, physical function and quality of life, post-intensive care length of stay and in-hospital mortality.

Results 34 participants were randomly allocated to the training group and 36 to control. The training group demonstrated greater improvements in inspiratory strength (training: 17%, control: 6%, mean difference: 11%, p=0.02). There were no statistically significant differences in FRI (0.03 vs 0.02, p=0.81), physical function (0.25 vs 0.25, p=0.97) or dyspnoea (−0.5 vs 0.2, p=0.22). Improvement in quality of life was greater in the training group (14% vs 2%, mean difference 12%, p=0.03). In-hospital mortality was higher in the training group (4 vs 0, 12% vs 0%, p=0.051).

Conclusions Inspiratory muscle training following successful weaning increases inspiratory muscle strength and quality of life, but we cannot confidently rule out an associated increased risk of in-hospital mortality.

Trial registration number ACTRN12610001089022, results.

INTRODUCTION

Invasive mechanical ventilation causes respiratory muscle weakness in intensive care unit (ICU) patients. After 18–69 hours of controlled mechanical ventilation, diaphragm proteolysis and atrophy occur and respiratory muscle weakness has been observed both while patients are mechanically ventilated and following successful extubation. Persistent respiratory muscle weakness may contribute to the residual dyspnoea, impaired physical function and poor quality of life observed in ICU survivors.

Inspiratory muscle training (IMT) is a relatively novel training strategy to improve inspiratory muscle strength in ICU patients. Threshold-based IMT is performed using a handheld device, which provides carefully titrated constant resistance on inspiration only, which is important in ensuring accurate titration of resistance as other IMT devices are flow-dependent, which means that the resistance varies with patient effort. Using a threshold IMT device the level of inspiratory pressure required to open the valve is increased over time to provide an ongoing training load as the patient’s inspiratory muscles become stronger. IMT improves respiratory muscle strength in patients undergoing invasive mechanical ventilation and a recent systematic review suggested that IMT performed prior to extubation enhances weaning success, although it does not appear to reduce rates of reintubation or likelihood of survival.

However, participation in threshold-based IMT while mechanically ventilated requires patients to be alert and cooperative with training. For many reasons, ICU patients may not be suitable candidates for IMT while ventilator-dependent (eg, due to sedation or delirium) and may only have sufficient cognitive capacity to participate in training once weaned from mechanical ventilation. Although case studies have shown improvements in inspiratory muscle strength with IMT, there have

Key messages

What is the key question?

Does inspiratory muscle training enhance recovery for patients who have been invasively ventilated for 7 days or longer?

What is the bottom line?

Two weeks of daily supervised inspiratory muscle training significantly improves inspiratory muscle strength and health-related quality of life in patients recently weaned from invasive ventilation.

Why read on?

Understand how this specific regime of inspiratory muscle training may be a useful adjunct to the medical management of patients in the postweaning period.
been no randomised trials of IMT in ICU patients in the postex-  
tubation period.

As residual inspiratory muscle impairment has been demon-  
strated in intensive care survivors ventilated for 7 days or longer,14  
we conducted a randomised trial to establish the effects of postex-  
tubation IMT in a heterogeneous sample of ICU patients who had  
been invasively ventilated for at least 7 days. Primary endpoints  
included inspiratory muscle strength and endurance following  
2 weeks of training. This 2 week time frame was selected pragm-  
tically, as pilot data indicated that most intensive care survivors  
remained inpatients during this 2 week period and would receive  
supervised physiotherapy. To date, no studies of IMT in ICU  
patients have included patient-centred outcomes or rates of  
readmission to ICU. Therefore, secondary endpoints included  
health-related quality of life, dyspnoea and functional levels after  
2 weeks of training. Post-intensive care length of stay, rate of inten-  
sive care readmission and in-hospital mortality were also explored.  
We hypothesised that in the IMT group, improvements in inspira-  
tory muscle strength and fatigue resistance would lead to reduced  
dyspnoea, improved quality of life and physical function, and  
lower rates of intensive care readmission and in-hospital mortality  
compared with the control group.15

METHODS

Design

We conducted a single-centre randomised trial with concealed  
allocation (computer-generated random-number sequence,  
managed by off-site administrative staff and obtained via tele-  
phone by the chief investigator following enrolment), assessor-  
blinding and intention-to-treat (ITT) analysis.15 The study was  
approved by the Australian Capital Territory Health Human  
Research Ethics Committee and the University of Queensland  
Medical Research Ethics Committee, and the published study  
protocol15 (trial registration ACTRN1261001089022) complied  
with the CONSORT guidelines for clinical trials.16

Participants, therapists, centre

All patients invasively mechanically ventilated for 7 days or  
longer were screened for eligibility. Patients were deemed eli-  
gible if they had been successfully weaned from mechanical ven-  
tilation (>48 hours), and within the 7 days following successful  
weaning they met the inclusion criteria (aged ≥16 years, able to  
provide informed consent, and alert and able to participate in  
training with a Riker17 score of 4). Patients were excluded if  
they had participated in IMT while mechanically ventilated,  
decided to decline, were pregnant, were not alert or able to  
participate with training, were experiencing significant pain or  
distress that interfered with breathing capacity and were deemed  
medically unstable or for palliation (ie, death likely in the next  
few weeks). Based on a priori power calculations, a total of 70  
participants were required to detect a 0.10 change in the  
primary outcome measures with a power of 0.80 (inflating  
group size by 15% to allow for known mortality of 12.8%)15.  
Although the minimal clinically important difference in  
maximum inspiratory pressure (MIP) scores has not been estab-  
lished in this patient group, the 0.10 change level was selected  
based on previous studies of inspiratory muscle strength and  
fatigue resistance in intensive care survivors3  
4 to allow comparisons to be drawn between studies. All participants provided  
informal consent to participate in the study.

Training was supervised by registered physiotherapists specif-  
ically trained in delivering IMT as described in our previously  
published protocols.13 15 Therapists could not be blinded to  
group allocation. The study was conducted in an Australian  
tertiary hospital (Canberra Hospital) where usual intensive care  
practice includes minimal sedation and early proactive mobilisa-  
tion.18 A second site was also included (Calvary Hospital);  
however, no patients were recruited from this site due to failure  
to meet eligibility requirements.

Intervention

Participants were randomised to receive either usual care  
(control group) or IMT in addition to usual care (IMT group)  
for 2 weeks following enrolment. Usual care physiotherapy  
included an individually tailored and supervised programme of  
interventions, which included any of the following: assisted  
mobilisation, secretion clearance treatments including positive  
expiratory pressure techniques, deep breathing exercises without  
a resistance device and upper and lower limb exercises.  

IMT was performed using the threshold IMT inspiratory  
muscle trainer (threshold IMT device HS730, Respironics, New  
Jersey, USA). This device was used with the mouthpiece, or a flex-  
ible connector if required to attach to a tracheostomy (figure 1).  
Where a tracheostomy remained in situ, IMT was always per-  
formed with the cuff inflated to ensure accurate loading. The  
physiotherapist prescribed an intensity of 50% of MIP for the  
first training set, but then quickly increased this to the highest tol- 

erable intensity that allowed the participant to just complete the  
sixth breath in a set of six breaths, with five sets of six breaths  
completed each session. Patients were allowed to rest between  
sets until they felt ready to commence the next set, which was  
typically less than 1 min of resting. The intensity was increased  
daily by the physiotherapist across the training period to provide  
an adequate training stimulus. This was achieved by manually  
increasing the threshold resistance by 1–2 cm H2O until the par-  
cipant could only just open the poppet valve on the sixth breath  
in each set. Training commenced on the day of enrolment and  
continued once daily (weekdays only) for 2 weeks. A sham  
device was not used for comparison as previous studies of IMT  
have found that the sham device may provide a training effect in  
participants with very low baseline strength.19

Measures

Primary endpoints

Measures of inspiratory muscle performance were recorded on  
enrolment and at the end of the intervention period 2 weeks

Figure 1 Inspiratory muscle training via a tracheostomy. Note the  
flexible tubing connecting the inspiratory muscle trainer to the closed  
suction device.
later by six specifically trained research nurses blinded to group allocation. Inspiratory muscle strength was assessed as MIP measured as previously described\(^5\) using a portable MicroRPM Respiratory Pressure meter (CareFusion, San Diego, USA) in accordance with the protocol described by the American Thoracic Society and European Respiratory Society.\(^5\) This device has been shown to have excellent reliability in measuring MIP in non-ventilated participants (intraclass correlation coefficient 0.83–0.90).\(^5\) Raw MIP scores were normalised using the method described by Evans and Whitelaw\(^25\) and have been presented as percentage of predicted values to account for known variation of MIP with age and gender. Inspiratory muscle fatigue was measured using the fatigue resistance index (FRI) technique described by Chang and colleagues,\(^5\) based on the maximum incremental threshold loading test described in the American Thoracic Society/European Respiratory Society guidelines.\(^25\) The prespecified endpoint was the between-group difference in change in outcome measures (ie, the change from enrolment to 2 week follow-up values).

Secondary endpoints

Measures of quality of life, dyspnoea and physical function were completed on enrolment and 2 weeks later. Quality of life was measured using the SF-36v2 tool (acute 1 week time frame) (under license Quality Metric USA) and the EQ-5D-3L tool (under license EuroQol International). These tools were administered by research nurses blinded to group allocation. The SF-36 tool has demonstrated reliability, responsiveness, construct and criterion validity and is responsive to clinical improvement in an intensive care population.\(^24\) The EQ-5D-3L tool has also been used in intensive care patient follow-up\(^23\) and is likely to give a more general measure of health-related quality of life than the SF-36.

Dyspnoea was measured using a Modified Borg Dyspnoea scale, where dyspnoea is a patient-reported categorical score out of 10, which has acceptable reliability and validity in patients undergoing mechanical ventilation.\(^26\) Dyspnoea was recorded both at rest (sitting comfortably in the chair or bed) and during exercise (the peak exercise activity experienced in the previous 24 hours) by research nurses blinded to group allocation.

Functional level including mental status, bed mobility, transfers and mobility was assessed using the acute care index of function (ACIF),\(^27\) which has excellent inter-rater reliability in ICU patients.\(^28\) Scores on enrolment were completed by physiotherapists blinded to group allocation; however, follow-up ACIF scores were recorded by the treating physiotherapist who was not blinded to group allocation.

Other secondary endpoints included rate of ICU readmission, requirement for reintubation, post-ICU hospital length of stay and in-hospital mortality. These data were extracted from hospital databases by research nurses blinded to group allocation. Post hoc analysis of participants who died during the hospital admission included retrospective calculation of the risk of death based on acute physiology and chronic health evaluation (APACHE II) scores.

Data analysis

The ITT population was defined as all 70 randomised participants. The per-protocol population was defined as all participants with both enrolment and 2 week follow-up data. All analyses were repeated in both the ITT and per-protocol populations. Paired t-tests were used to compare within-group differences. Mixed linear models were used to assess the between-group difference of the changes between enrolment and follow-up measures, including age and APACHEII scores as covariates. Diagnostic plots (predicted means vs Pearson’s residuals) were generated to assess model assumptions. Mortality data were analysed using \(\chi^2\) and Fisher’s exact test. Statistical significance was set as \(p<0.05\). All analyses were done using SPSS V21.

RESULTS

Flow of participants through the study

The flow of participants is presented in figure 2. Between February 2011 and August 2015, 70 participants were recruited to participate in the study with 34 allocated to the IMT group and 36 to the control group. Participant characteristics are presented in table 1 and are similar between IMT and control groups, except for a higher percentage of male participants in the IMT group (71% vs 58%).

The most frequent reason for exclusion from the study was poor neurological status with resultant inability to provide consent. Six participants were lost to follow-up in each group, most commonly due to transfer to another hospital within the study period. Two participants died within the intervention period, both in the IMT group. Two participants died after the intervention but prior to hospital discharge, both in the IMT group. Thus, the total mortality in the treatment group was 12%, compared with 0% in the control group. Where patients were lost to follow-up regarding the primary outcome measures, other postintervention secondary measures were still obtained through hospital databases (table 3).

Compliance with trial protocol

In the IMT group, across the 34 participants, 85% of all intended IMT treatments (potential 10 treatments for each patient) were completed. Twenty-three participants (67%) completed more than 90% of the prescribed IMT sessions, while two (6%) participants completed 20% or less of the prescribed IMT sessions. The most frequent reason for lack of completion was participant refusal due to generalised fatigue. IMT was generally well tolerated and no adverse effects were reported during or immediately after training in any participant. No participants in the control group inadvertently received IMT. Two participants (both in the control group) were discharged home prior to completion of the 2 week intervention period; however, they attended the outpatient department for completion of outcome measures.

Effect of intervention

The ITT and per-protocol analyses yielded entirely congruent results; therefore, only the ITT analysis is presented. Changes in outcome measures within and between groups are summarised in online supplementary table E1 and table 2. MIP improved in both groups, with a statistically significant greater increase in the IMT group than the control group (17% in IMT group vs 6% in control, \(p=0.024\)) (figure 3A). No statistically significant change in FRI was observed for either group at the end of the study period (0.03 vs 0.02, \(p=0.81\)) (figure 3B).

Both quality-of-life measures demonstrated statistically significant improvements from baseline in the IMT group only (mean difference=14, \(p=0.001\) for EQ3D; mean difference=0.08, \(p=0.001\) for SF-36) (figure 4A, B). Between groups, the difference in EQ5D scores was higher in the IMT group (14 vs 2, \(p=0.034\)). There was no statistically significant difference in SF-36 scores, although the point estimates suggested a potential benefit (mean difference=0.05, 95% CI=–0.01 to 0.10).

Both groups demonstrated significant improvements in functional outcomes, as measured by the ACIF (figure 4C); however,
these improvements did not differ between groups (0.25 vs 0.25, p=0.974). Changes in dyspnoea scores both at rest and during exercise were not statistically significant either within or between groups across the intervention period.

There were no significant differences between groups for post-ICU length of stay, reintubation rate or ICU readmission (table 3). However, in-hospital mortality was higher in the IMT group (p=0.051) with four deaths, two during the 2 week intervention period and two following the intervention period (see online supplementary table E2 for details regarding causes of death).

**DISCUSSION**

We have shown for the first time that in the postextubation period, participants who complete 2 weeks of IMT have greater improvement in respiratory muscle strength than those who do not train. This is congruent with previous studies of IMT in mechanically ventilated patients and with the rapid strength gains within 2 weeks of commencing IMT previously described in healthy cyclists (eg, increased MIP scores by 8.4%29). It is possible that some of the apparent strength gains could be attributable to a learning effect, given the similarity between the IMT technique and the MIP testing manoeuvre. However, in ICU patients rapid atrophy has been observed in both skeletal and respiratory muscles within the first few days of admission. With an adequate training stimulus, some of these changes could be reversible within a relatively short time frame, although it appears that some individuals respond to training more than others (see online supplementary figure E1).

Regardless of the underlying mechanism of improvement, the

---

apparent strength gains in this cohort translated into benefits in quality of life, which is arguably a more important patient-centred outcome than inspiratory muscle strength.

Our inability to demonstrate an improvement in inspiratory muscle endurance in the IMT group is somewhat surprising, as IMT has been shown to increase proliferation of both type 1 and type 2 inspiratory muscle fibres and endurance benefits of IMT have been reported after 8 weeks of training in patients with COPD after 11 weeks of training in athletes and after 4 weeks of training in recreationally active people. While it is possible that the specific training regime employed in our study translates into strength benefits alone, it is more likely that the duration of training was insufficient to affect a measurable improvement in endurance, or that the FRI is insufficiently sensitive to detect subtle changes in endurance over such a short time frame. A more sustained constant loading test may have better elucidated changes in inspiratory muscle endurance; however, our experience with these participants resonated with that of Chang and colleagues found a limited tolerance to exercise/10, which provided an advantage early in this trajectory.

Although the IMT group expressed improved quality of life using the EQ5D tool, the effect was less marked when assessed by the SF36. This may reflect difficulty in completing all components of the longer SF36 questionnaire. One of the challenges in ICU outcomes research is the extent of residual cognitive impairment and fatigue on a participant’s ability to complete lengthy quality-of-life assessment tools. The reasons for improved quality of life in the absence of a demonstrated effect on respiratory endurance, dyspnoea or functional level remain unclear.

Improvements in inspiratory muscle strength did not have a clinically or statistically significant impact on the other patient-centred outcomes in this study. While physical function improved similarly in both groups, it is likely that other aspects of treatment (eg, whole body exercise and gait retraining) had a clinically important role beyond the ICU stay but it is possible that IMT provides an advantage early in this trajectory.

ICU, intensive care unit; IMT, inspiratory muscle training.
stronger influence on recovery of physical function than IMT. The fact that both groups improved in terms of physical function may reflect the high standard of usual care in this unit, which includes early rehabilitation and mobilisation. Thus, the findings of this study may only be generalisable to acute settings where early mobilisation and rehabilitation are the norm. Furthermore, the failure of IMT to significantly affect reintubation rates or length of stay may be attributable to the small sample size, as the effect size of IMT may be very small in relation to the many other variables that impact on these clinically significant outcomes. Future studies

of IMT in the postweaning period should be adequately powered to further clarify these relationships.

The difference in in-hospital mortality between groups was unexpected, although the mortality in the IMT group (12%) was close to that anticipated in the trial design (12.8%). To our knowledge, no increase in mortality has been reported with IMT in any population to date, including ventilated ICU patients, or patients with COPD or heart failure. As summarised in online supplementary table E2, none of the deaths appeared to be related directly to IMT or respiratory complications. Given the small number of study participants and heterogeneity of diagnoses, further study of the impact of IMT on in-hospital mortality is indicated before robust conclusions about mortality can be drawn.

Limitations of this study include a loss to follow-up of 17%, which should have been partly offset by the planned sample size augmentation of 15% to account for anticipated mortality. A lack of follow-up of primary outcomes beyond 2 weeks is another limitation. Moreover, some patients may benefit from ongoing IMT beyond a 2 week training period, particularly as most did not return to 100% of predicted MIP values during this study. In patients with COPD, IMT has longer-term benefits including lower rates of hospitalisation over a 12 month period. It is possible therefore that IMT in the postextubation period has ongoing effects, which should be assessed further.

With regard to the training device, a ceiling effect was problematic in two participants whose MIP exceeded 82 at baseline. As the maximum resistance setting on the device is 41 cm H2O, it was impossible to provide training at greater than 50% of MIP in these two participants. While all other participants commenced at 50% MIP intensity during the training period, 16 participants (47%) achieved the 41 cm H2O maximal setting on the device at some point during the 2 week period, limiting further incremental training. Thus, our study may have underestimated the potential impact of IMT. In future studies of IMT we recommend using a device with the capacity to provide higher training intensities, such as an electronic device. Furthermore, future studies may target those with identifiable strength deficits, as these may constitute a subgroup, which is most likely to benefit from training, while those with high baseline values have probably diluted the potential benefits of training in our cohort.

This study is the first to demonstrate the value of IMT for patients in the postextubation period. IMT can be considered an effective strategy to reverse some of the residual inspiratory muscle weakness, which is common following prolonged mechanical ventilation, and may enhance quality of life in these patients with just 2 weeks of training. Future studies of ICU patients in the postextubation period should further explore the impact of IMT on quality of life, as well as the longer term effects of IMT in this group, including effects on mortality.
