A 65-year-old obese male, with no other comorbidities, was admitted to our intensive care unit for acute respiratory failure due to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. The patient was mechanically ventilated (intermittent positive pressure ventilation auto-flow mode with tidal volume of 6 mL/kg, positive end expiratory pressure (PEEP) 12 cmH2O, respiratory rate 20 breaths/min and fractional inspired oxygen (FiO2) to the lowest level to maintain arterial pO2 in a range of 55–60 mm Hg) for 7 days before his condition abruptly worsened. He became haemodynamically unstable with changes in the cardiac electrical activity and hypotension unresponsive to catecholamines. An initial plain chest X-ray revealed widespread subcutaneous emphysema. Chest-CT demonstrated a massive tension pneumomediastinum. Mediastinal decompression was performed via two incisions, one at the sternal notch and one below the xiphoid process (figure 1). The posterior wall of the sternum was liberated of pericardial fat using blunt dissection with fingers and peanut sponge forceps. A chest tube was placed from the inferior incision into the pretracheal space and connected to a closed system allowing permissive hypercapnia and increasing the oxygen percentage of the airflow to denitrogenate the mediastinal space.1 Due to the high number of patients being treated with this type of ventilation, we are seeing an increasing number of tension pneumomediastinum cases.

Air leakage from the alveolus occurs due to a pressure gradient between the alveolus and the perivascular sheaths. If the pressure gradient is maintained, the air tracks along the vascular sheaths to the mediastinum.1 2 Due to increasing mediastinal pressure a compression of the great vessels occurs, leading to decreased venous return, hypotension and finally to cardiac collapse.3 The initial diagnosis may be difficult due to associated subcutaneous emphysema that covers the underlying disease on chest X-ray. Treatment may be conservative, reducing the airway pressures, allowing permissive hypercapnia and increasing the oxygen percentage of the airflow to denitrogenate the mediastinal space.1 2 Considering the fragility of patients with COVID-19, this approach is often insufficient, thus surgery may be necessary. In our experience, the approach we

described immediately improves the clinical condition of the patient with very low risks of complications, even for an inexperienced thoracic surgeon.\(\textbf{figure 2}\)
