Lung epithelial cells interact with immune cells and bacteria to shape the microenvironment in tuberculosis

Amy M de Waal,1 Pieter S Hiemstra,2 Tom HM Ottenhoff,1 Simone A Joosten,1 Anne M van der Does2

ABSTRACT
The lung epithelium has long been overlooked as a key player in tuberculosis disease. In addition to acting as a direct barrier to Mycobacterium tuberculosis (Mtbd), epithelial cells (EC) of the airways and alveoli act as first responders during Mtbd infections; they directly sense and respond to Mtbd by producing mediators such as cytokines, chemokines and antimicrobials. Interactions of EC with innate and adaptive immune cells further shape the immune response against Mtbd. These three essential components, epithelium, immune cells and Mtbd, are rarely studied in conjuction, owing in part to difficulties in coculturing them. Recent advances in cell culture technologies offer the opportunity to model the lung microenvironment more closely. Herein, we discuss the interplay between lung EC, immune cells and Mtbd and argue that modelling these interactions is of key importance to unravel early events during Mtbd infection.

INTRODUCTION
While breathing, the entire surface of the lungs is exposed to numerous foreign particles. These include micro-organisms such as bacteria, viruses and fungi. Despite the abundance of microbes that enter the lung, infections are relatively rare. This is the result of a tightly regulated host defence system, comprised of specialised epithelial responses, innate and adaptive immunity and the microbiota that synergistically provide protection against infectious agents invading the lung. However, failure or microbial evasion of these defence systems may result in pulmonary infections.

Tuberculosis (TB), caused by Mycobacterium tuberculosis (Mtbd), has been regarded a pandemic by the WHO for decades. Mtbd has infected approximately a quarter of the world population and kills over 1.5 million people every year, making it the leading cause of death from a single infectious agent over the last two centuries. A proportion of individuals exposed to Mtbd remains uninfected, or possibly clears the infection at an early stage. In those who do acquire the infection, Mtbd can persist for decades without causing disease, a condition known as latent TB infection.

Mtbd bacilli hide deep in the lungs, complicating detection. Therefore, relatively little is known about the early stages of infection and the key players involved. According to the field’s current understanding, Mtbd preferentially targets macrophages, in particular those that reside in the alveoli, and employs various strategies to survive intracellularly. The primary pathology resulting from these infected macrophages is the formation of granulomas, organised structures consisting of various immune cells that contain the infection. The initial infection and disease progression of TB are summarised in detail in figure 1. This focus on the granuloma disease stage, however, does not yet take into account the role of the lung epithelium, which represents a major part of the pathogens’ microenvironment. Moreover, lung epithelial cells (EC) directly interact with alveolar macrophages (AM) and orchestrate the macrophage-driven immune response. Other immune players involved in TB control may also behave differently in the presence of EC. Therefore, local interactions between Mtbd, the lung epithelium and the immune system are of particular interest to understand the initiation and subsequent pathophysiology of the disease. Finally, in vitro models used in many studies do not recapitulate the complex microenvironment surrounding Mtbd infections. Interactions between epithelium, immune cells and Mtbd and the importance of modelling the Mtbd infection niche in vitro will be discussed in greater detail in this review.

KEY PLAYERS IN RESPIRATORY MYCOBACTERIAL IMMUNITY
Epithelial–Mtbd interactions
Current findings suggest that the epithelium is less susceptible to infection with Mtbd than AM, which may have contributed to the relatively unexplored role of lung epithelium in antymycobacterial immunity. The cellular composition of epithelium varies depending on the region of the lung, and it may therefore respond differently to mycobacterial challenge. Here, we distinguish between airway and alveolar epithelium when discussing lung epithelial contributions to mycobacterial immunity.

The alveolar epithelium consists of large type I alveolar cells (AEC1) responsible for gas exchange and cuboidal AEC2 responsible for secreting functions (figure 2), including surfactant production. AEC2 also have a progenitor function, as they can self-renew and give rise to AEC1 and other subsets. The airway epithelium, on the other hand, is pseudostratified and mostly consists of multiciliated cells and secretory goblet cells and club cells, interspersed with neuroendocrine cells and basal cells (figure 3). More recently, other small cell populations have been discovered: tuft cells and ionocytes. Basal cells act as progenitor cells and are mainly responsible for self-renewal of the airways.
State of the art review

Upon inhaling aerosolized Mtb from cough droplets produced by infected individuals, Mtb passes through the trachea and bronchi into the distal airways and alveoli. There, it may be phagocytosed by tissue-resident alveolar macrophages (AM) and dendritic cells (DC). However, Mtb interferes with regulatory membrane trafficking (PGP1) and ATPase H+ proton-pumps to arrest phagosomal maturation at an early stage. Next, Mtb gains access to the cytosol by rupturing the phagosome, a process dependent on the ESX-1/1773 protein secretion system and virulent mycobacterial lipids. Detection of mycobacteria by cytosolic and cell surface receptors initiates the innate and adaptive immune responses that follow, including cytokine secretion, and activation of the inflammasome and autophagic machinery. Lastly, Mtb controls host cell death, favoring necrosis, which promotes its dissemination (C).

Epithelial sensing of Mtb

EC express a large repertoire of pattern recognition receptors (PRRs) to sense micro-organisms. These include the membrane-bound Toll-like receptors (TLRs) and C-type lectins, cytosolic nucleotide-binding oligomerization domain (NOD)-like receptors and nucleic acid sensors (table 1). On contact with pathogens, PRRs are activated and EC secrete an array of pro-inflammatory and anti-inflammatory cytokines as well as chemokines which attract different immune cell subsets (table 1). Interestingly, CD4+ T cell-associated type 1 helper (Th1) and Th2 cytokines were also shown to regulate expression of different TLRs in primary airway EC (PBEC), illustrating the complex cytokine milieu required to coordinate appropriate responses to pathogens. In addition, antimicrobial peptides (AMPs) with direct effects on pathogens are secreted by airway and alveolar epithelium (table 1). For example, β-defensin-2 (hBD2) expression can be upregulated by vitamin D, and physiological vitamin D levels contributed to restriction of Mtb or Mtb/HIV replication in macrophages. Interestingly, vitamin D-induced interleukin-1 (IL)-1β secretion by macrophages stimulated antimycobacterial capacity of primary small airway EC in a coculture model and reduced bacterial burden. These effects were dependent on epithelial production of hBD2 and IL-1 receptor type 1 signalling. On the other hand, IL-1-mediated crosstalk between EC and Mtb-infected AM was shown to promote dissemination of infected cells. Other products secreted by EC might also have indirect effects on mycobacteria. For example, various hydrolases secreted in the alveolar surfactant were shown to modify the Mtb cell wall. This resulted in a significant decrease in Mtb association with and infection of macrophages.

Different epithelial cell types employ various defence strategies that contribute to clearing infections. Secretory goblet cells produce mucus which is mechanically transported up the airways by ciliary motion of multiciliated cells, resulting in physical removal of the pathogen. AEC2 secrete surfactant containing the aforementioned antimicrobial mediators and reactive oxygen species, to keep pathogens, including Mtb, at bay. EC can therefore be considered sentinels, initiators and modulators of in response to mycobacterial infection. LL-37 and β-defensin-2 (hBD2) expression can be upregulated by vitamin D, and physiological vitamin D levels contributed to restriction of Mtb or Mtb/HIV replication in macrophages. Interestingly, vitamin D-induced interleukin-1 (IL)-1β secretion by macrophages stimulated antimycobacterial capacity of primary small airway EC in a coculture model and reduced bacterial burden. immunity, thus contributing directly to infection-driven pathogenesis, including the regulation of innate and adaptive immune responses.

Epithelial infection by Mtb

Besides sensing pathogens and acting as an early warning and defence system, EC of the lung can also be directly infected by mycobacteria. PBEC seemed relatively insensitive to infection with Mtb, whereas EC of the bronchial epithelium were more susceptible to Mtb infection. Early reports described successful infection of the cell line A549 by Mtb and the attenuated vaccine strain Mycobacterium bovis Bacille Calmette-Guérin (BCG). Moreover, both species were able to migrate across a bilayer model of A549 and endothelial cells, in the absence of apical or basal binding of Mtb. Cytokines produced by alveolar type 2 cells help activate AM, which migrate towards Mtb bacilli. (3) Mtb is phagocytosed by AM and transported across the alveolar barrier to underlying tissue. (4) Infected AM die and attract more macrophages, monocytes from the bloodstream, neutrophils and adaptive immune players such as T cells, B cells and dendritic cells (DCs). This marks the start of granuloma formation. This figure was created with BioRender.com.

These studies only included A549 cells and validation in primary alveolar EC will be important. EC are non-professional phagocytes, although mechanisms of mycobacterial adherence and internalisation by EC have been described. The proteoglycan syndecan 4 (SDC4) was identified as an attachment receptor for BCG on alveolar A549 cells, and this interaction involved host SDC and mycobacterial heparin-binding haemagglutinin adhesin. Furthermore, SDC4-knockout mice were more resistant to Mtb H37Rv colonisation. Other adhesins expressed by Mtb that directly bind EC are malate dehydrogenase and ESAT-6, which may also facilitate dissemination of mycobacteria by epithelial barrier disruption via cell lysis. Inside EC, Mtb is initially processed via the phagocytic pathway, where it is localised in late endosomal compartments in alveolar and airway epithelium. However, fusion of Mtb-containing compartments with lysosomes was blocked in EC, as is the case in macrophages. In A549 cells, Mtb was found inside vesicles labelled with the autophagy marker LC3, indicating that Mtb is processed via the autophagy pathway.

Epithelial–immune cell interaction during Mtb infection

Innate immune cell activation by Mtb-exposed epithelium

Sometimes the direct response mounted by the lung epithelium is not sufficient to eradicate invading pathogens. EC also secrete cytokines, chemokines and antimicrobials to attract and activate immune cells. Cytokines produced by alveolar type 2 cells help activate AM, which migrate towards Mtb bacilli. (3) Mtb is phagocytosed by AM and transported across the alveolar barrier to underlying tissue. (4) Infected AM die and attract more macrophages, monocytes from the bloodstream, neutrophils and adaptive immune players such as T cells, B cells and dendritic cells (DCs). This marks the start of granuloma formation. This figure was created with BioRender.com.

Figure 2 Early Mtb infection events in the alveoli. A model of early Mtb (Mycobacterium tuberculosis) infection events in the alveoli based on the field’s current understanding discussed in this review. Mtb enters the alveolus (1) and is subsequently sensed by alveolar type 2 cells, which produce cytokines, chemokines and antimicrobials (2). Mtb also directly infects alveolar type 2 cells and alveolar macrophages (AM). Cytokines produced by alveolar type 2 cells help activate AM, which migrate towards Mtb bacilli. (3) Mtb is phagocytosed by AM and transported over the alveolar barrier to underlying tissue. (4) Infected AM die and attract more macrophages, monocytes from the bloodstream, neutrophils and adaptive immune players such as T cells, B cells and dendritic cells (DCs). This marks the start of granuloma formation. This figure was created with BioRender.com.

Figure 3 Interactions between Mtb, epithelium and immune cells in the airways. A model of interactions between Mtb (Mycobacterium tuberculosis), epithelial cells (EC) and immune cells in the airways based on findings discussed in this review. (1) Mtb is sensed by EC via pathogen recognition receptors. Cytokines, chemokines and antimicrobials are released into the lumen of the airway. (2) Cytokines released by infected EC attract immune cells. In this case, CXCL5 attracts neutrophils to the site of infection. (3) Infected EC present antigens to T cells via major histocompatibility complex class I (MHC-I) and MHC-II. T cells become activated and produce interferon gamma (IFN-γ). (4) Microfold cells transport Mtb through the epithelial barrier to the underlying inducible bronchus-associated lymphoid tissue (iBALT). Presence of M cells is not yet verified completely in humans. Dendritic cells (DCs) sense Mtb and activate T cells in the BALT. (5) Infected macrophages and monocytes produce cytokines and may activate EC to produce more cytokines in a positive feedback loop. This figure was created with BioRender.com.

inflammatory mediators that may affect the type and magnitude of the immune response that follows. Culture of the monocyte cell line U937 in presence of Mtb-infected A549 cells resulted in reduced Mtb-triggered TLR signalling in the monocytes, compared with infected monocytes alone.33 This suggests that EC influence the inflammatory response of immune cells. Additionally, submerged PBEC cultures produced anti-inflammatory cytokines IL-10 and IL-22 in response to BCG infection.44 This suggests that airway and alveolar EC act as moderators of inflammation during mycobacterial infection. In line with these observations, some studies found increased levels of IL-10 in sputum of patients with TB. This correlated with higher Mtb antigen burden,45 suggesting that IL-10 could undermine effective clearance of Mtb. This effect is likely caused by the negative influence of IL-10 on Th1 T cells and macrophages,46 which play a pivotal role in protective immunity against Mtb.

Neutrophils are attracted more strongly to PBEC infected with Pseudomonas aeruginosa (common in cystic fibrosis patients) than with a non-pathogenic Escherichia coli strain.47 In this manner, EC filter pathogenic signals, levelling subsequent immune activation by moderating PRR expression.48 A tightly regulated balance is important as EC recruiting too many leukocytes risk excessive inflammation and lung injury as a result. Neutrophils, for example, are considered protective during early Mtb infections, but pathogenic at later stages where they are associated with poor prognosis. CXCL5 is a chemokine produced by EC and important in the initial recruitment of neutrophils. Cxcl5−/− mice exhibited enhanced survival after Mtb infection compared with wild-type mice. This resistance to Mtb infection was due to impaired neutrophil recruitment, which reduced pulmonary inflammation. This suggests that excessive epithelial-derived CXCL5 is critical for leukocyte-driven destructive inflammation in TB.49

In turn, innate immune cells influence the rate of infection in EC. Mtb and BCG first cultured intracellularly in murine macrophages had a higher association with A549 cells and infected a higher percentage of them,55 suggesting enhancement of mycobacterial virulence after exposure to the intracellular environment of macrophages. By contrast, Mtb and M. avium growth in the macrophage cell line Mono-Mac-6 was reduced by A549 cell-derived soluble factors including TNF-α and granulocyte-macrophage colony stimulating factor (GM-CSF).50 Lastly, in a contact-independent model, PBEC were activated by Mtb-infected monocytes to produce antimicrobials and cytokines that were not inducible by direct infection of the bronchial cells themselves,52 highlighting the crosstalk between epithelial and immune cells.

**Antigen presentation and T cell activation by the epithelium**

Antigen presentation to T cells is required for activation of adaptive immune responses against Mtb. While this role is often fulfilled by DC, there is evidence for antigen presentation to T cells by EC. Several studies have identified expression of major histocompatibility complex class II (MHC-II) molecules on human bronchial (figure 3) and alveolar EC, which would imply direct activation of CD4+ T cells by the epithelium.53-55 Human nasal and bronchial EC were able to stimulate allogeneic T cells, an effect abrogated by addition of anti-MHC-II antibodies.56 Functional MHC-II has also been identified on pulmonary EC of other species. Rats constitutively expressed MHC-II on AEC2, and to a lower degree on bronchial epithelium, suggesting cell type-specific regulation of expression.54 Murine AEC2 also expressed MHC-II and were able to present antigens to primed CD4+ T cells when infected with Mtb.55 Furthermore, expression of costimulatory molecules has been demonstrated in human epithelium and appears to be cell type specific. CD86 was found on both PBEC and A549 cells.52,56 CD80, on the other hand, was only found on alveolar EC.56

CD8+ T cells play an additional role in protection against intracellular pathogens such as Mtb. In a study by Harriff et al, interferon γ (IFN-γ) production by CD8+ T cells was stimulated by bronchial epithelium following Mtb infection.42 These authors also showed that the bronchial epithelial basal cell line BEAS-2B activated several Mtb-specific, classically (HLA-B45) and non-classically (HLA-E, MR-1) restricted T cell clones to a higher degree than DCs after infection with Mtb, as measured by IFN-γ producing T cells. This is a surprising observation, since bronchial epithelium was infected with lower efficiency compared with DCs.

Further studies highlighting the importance of EC in shaping T cell responses studied BCG vaccination in mouse and rhesus macaque models. In these studies, mucosal vaccination-induced superior protection against Mtb compared with intradermal vaccination.57 Perdomo et al described the recruitment of significantly higher frequencies and absolute numbers of effector memory T cells (TEm) and tissue-resident memory T cells (TRM) after mucosal vaccination compared with subcutaneous vaccination.58 Particularly the TEm subset has been suggested to confer protection against infections, including Mtb.59 TRM cells are hardly detectable in the circulation, but abundantly present in tissues. Comparison of different administration routes showed substantially more antigen-responsive TRM cells in all lung parenchymal tissues after intravenous BCG immunisation.60 Furthermore, approximately 75% of all CD4+ and CD8+ T cells were TRM, following direct endobronchial instillation of BCG.

Other types of adaptive immune cells may participate in anti-Mtb immunity too. Mucosal-associated invariant T (MAIT) cells were found enriched in the airways,61 and Mtb-infected airway EC were capable of inducing IFN-γ production from MAIT cells.62 Furthermore, BCG vaccination induced transient expansion of the peripheral MAIT cell population in humans and specifically activated MAIT cells in non-human primates.63,64 Few studies to date looked at interactions between lung epithelium, regulatory T cells and innate lymphoid cells (ILCs). In Mtb-infected mice, IL-22-producing ILC3s prolonged survival and prevented epithelial cell damage.65 Interestingly, EC may also regulate IL-17-producing T helper cells (Th17) via a complex feedback loop. The enzyme indoleamine-2,3-dioxygenase (IDO) is expressed by lung EC. Following IFN-γ release by T cells, downstream IDO products secreted by EC were found to selectively inhibit IL-17 production by Th17 cells.

**Microfold cells (M cells) transport Mtb to bronchus-associated lymphoid tissue (BALT)**

M cells are specialised EC present in areas of the airways where inducible BALT (iBALT) exists or can be induced.66 These specialised M cells transport macromolecules and microbes from the airway into the subepithelial region, a process called antigen transcytosis. Subsequently, these antigens induce maturation of immature DCs, which in turn activate naïve T cells residing in the iBALT. In mice, M cells enabled transport of particles and microbes, including Mtb, across the epithelial barrier.67 Scavenger receptor B1 on M cells was reported to bind the major Mtb virulence factor EsxA, facilitating Mtb adherence to and translocation through the epithelial layer in vitro.68 Furthermore, the TB granuloma is often surrounded by clusters of cells...
that are remarkably similar in structure to iBALT and perform tertiary lymphoid functions.66 iBALT is not present in healthy adults and is formed following a period of inflammation in the airways. However, iBALT induced by a previous unrelated infection or allergic reaction, smoking or chronic inflammation (asthma) may persist for weeks or longer.66,69 Even so, it is unlikely that M cells and iBALT are present in healthy individuals when Mtb first enters their lungs, so the importance of M cells in initial Mtb infection biology is debatable. Although M cells have been induced in human bronchial epithelial cell lines68 and their presence was demonstrated in multiple animal models, it has not been verified whether M cells or comparable cells do exist in human lungs. Taking these considerations into account, M cells could potentially function as gateways for Mtb (figure 3), though their relevance to human Mtb infection biology requires further investigation.

The findings discussed so far support the view of a tightly regulated interplay between the epithelium, immune cells and Mtb during different stages of infection. The next section of this review shall focus on possibilities to integrate these three key players in models for in vitro studies.

**IMPORTANCE OF COMPLEX MICROENVIRONMENT REPRESENTATION FOR MECHANISTIC STUDIES**

Studying early phases in Mtb infection in humans in vivo is complicated; the lung is not readily accessible and patients are often diagnosed at later stages of infection. Though animal models have contributed valuable scientific insights in the past, most are not very representative of human lung physiology. For example, epithelial cell composition varies between similar regions of human and mouse lungs as well as the distribution of cartilage.70 A caveat for the zebrafish model is the fact that it does not possess lungs. In vitro models provide an alternative to study Mtb infections more closely. However, these models often lack sufficient complexity to represent the microenvironment of the lung. For example, immortalised or tumour cell lines of lung epithelia generally consist of one cell type and are derived from one donor; depending on culture conditions they are poorly or not at all differentiated. In addition, most culture systems lack crossstalk with other players. Recent developments in cell culture technology have resulted in a larger array of in vitro models with higher levels of complexity to mimic the desired microenvironment. Though studies using such models in combination with Mtb are currently scarce, we argue that they are of great importance in further unravelling early TB infection phases.

**Air-liquid interface (ALI) cultures of (primary) lung EC**

ALI cultures consist of an epithelial cell layer grown on a permeable membrane. Cells are exposed to air on their apical side, while nutrients are supplied from the basal side, promoting polarisation in all epithelial cultures and differentiation in airway EC cultures. This model allows EC to be cultured in a way that resembles their physiological environment more closely than submerged cultures.71

Infectious agents and immune cell subsets can be added to the air-exposed (apical) side or to the medium (basal side) of the ALI model. Several studies have used Mtb and BCG to infect bronchial ALI cultures, but encountered some issues. The epithelium was resistant to infection in models using primary material and cell lines.72 In one study, macrophages were integrated into the epithelial layer before infection, and the success of infecting the tissue seemed macrophage dependent. However, integration of macrophages also resulted in uncontrolled mycobacterial growth.61 Seeding Mtb-infected macrophages together with uninfected monocytes before addition of the bronchial epithelial cell line 16HBE on top resulted in clustering of monocytes around infected macrophages.73 This might indicate early-stage granuloma formation. Alternatively, Mtb-infected macrophages may be introduced to the basal compartment of Transwell systems.41 While such methods do illustrate the multifunctionality of the ALI model, they bypass the epithelium as a first point of host-pathogen contact. Airway ALI models have been successfully infected with various bacteria, fungi and viruses, suggesting that bronchial EC are less susceptible to Mtb infection in comparison to other pathogens.

Alveolar ALI models may be more hospitable hosts to mycobacteria. Most studies use A549 cells to study Mtb infection rates and migration through the alveolar barrier. It should be noted that A549 cells can be cultured at ALI for a short period only, due to leakage through the cell layer during longer air exposure due to their limited ability to form a barrier. A549 cells are sometimes cultured as a bilayer with endothelial cells.74 Within 3 days, approximately 1% of Mtb inoculum migrated across such a bilayer model, while dissemination-attenuated strains such as BCG achieved less than 0.5% migration.75 This supports the view that macrophages or monocytes are not required to transport the bacteria across the alveolar barrier.

**Organoids**

Organoid cultures are three-dimensional (3D) models that recapitulate certain organ environments. They are self-organising and self-renewing structures generated from adult stem/progenitor cells isolated directly from a target organ or from embryonic or human induced pluripotent stem cells (hiPSC).76 Airway EC containing basal cells or AEC2 are isolated from the airways or alveoli, respectively, to generate organoids.77,78 They are grown in extracellular matrix gels to provide support for 3D growth.

Organoid models of the lungs are disadvantaged in the sense that no ALI can be established as the apical side of the cells is generally facing toward the lumen of the organoid which is filled with liquid and mucus. Apical pathogen exposure can therefore be challenging. To overcome this issue, pathogens can be injected into the lumen of organoids with a microinjector.77 Although this process is labor intensive, it creates a representative infection model by exposing cells’ apical side to pathogens. Immune cells can be added to microinjected organoid cultures, creating a coculture where immune cells and bacteria are separated by the epithelial barrier. However, since organoids are cultured in matrix gels, immune cells may have difficulty accessing the infected organoids. Finally, organoids can be sheared into pieces before pathogen addition, exposing both apical and basal sides of the cells,79 or the polarity of organoids can be reversed to have the apical side facing outwards.79

While many studies successfully used lung organoids to model SARS-CoV-2,76,79 and other viral infections, organoids have not been used extensively for host–pathogen studies with mycobacteria. Primary bronchial epithelial organoids microinjected with Mtb and cocultured with macrophages showed that Mtb remained viable inside the airway organoid lumen up to 21 days after injection, with approximately 2% of bacteria associating with EC.78 Additionally, within 3 days, monocyte-derived macrophages migrated towards the infected organoids, though they did not traverse into the lumen of the organoids. Other pathogens and leucocyte subsets have been used in different combinations cocultured with organoids of different organs including the intestines, gallbladder and brain.81 Collectively, these studies...
show that the organoid is an emerging *in vitro* model for host–pathogen interactions and merits further investigation regarding Mtb infections.

**Organs-on-chips**

Organs-on-chips aim to recreate *in vivo*-like tissue microenvironments having multiple compartments, including dynamically controlled flow of nutrients in the vascular compartment or stretching to mimic breathing-like motions of the lung. In addition, organs-on-chips require a smaller culture volume and fewer cells, while allowing precise control of microenvironmental parameters. A variety of lung-on-chip models have been developed over the past years in which EC are used in combination with vascular cells, immune cells derived from primary sources and/or hiPSC cell lines. Despite the rather novel and developing technology, cocultures with Mtb and other pathogens have already been reported. A recent study using a lung-on-chip model of murine alveoli demonstrated that alveolar surfactant played an essential role in controlling mycobacterial growth. A different study used a novel variant of the chip technology to model the immune compartment of granulomas, in combination with endothelial cells to model granuloma-associated angiogenesis. EC were not incorporated in this model, though further development could include the addition of EC and fibroblasts. Another *in vitro* granuloma model which was used to study anti-TB drug efficacy was comprised of primary human monocytes and T cells. These cells formed granulomas in a 3D matrix, but no EC were included in the model.

**Tissue explants**

Human lung tissue explants can be used to study Mtb infection, as they retain a high degree of tissue relevance. Tissue explants contain all relevant cell types, including myeloid cells and lymphocytes, as well as fibroblasts, endothelial cells and others. Precision cut lung slices (PCLS) are prepared by cutting thin sections of agarose-perfused resected tissue. They maintain the 3D architecture of the lung, and when embedded in specialised hydrogels can be kept in culture for at least 21 days. In PCLS cultures, Mtb and BCG localised near alveolar septa and were in proximity to AEC2. No evidence was found of infection of AEC2, though intracellular mycobacteria were observed in AM in this model.

Larger tissue explants have also been used for mycobacterial infection studies. In human tissue explants, alveolar EC are readily infected by Mtb. Cytokine expression was analysed in the alveolar epithelium and an array of leucocyte subsets present in the tissue, including AM, natural killer (NK) cells, γδ T cells, MAIT cells and ILCs. Another study confirmed the localisation of Mtb in alveolar EC and found approximately 3.5% of the infected cells were AEC2, while over 74% of infected cells were macrophages.

While tissue explants are arguably the most representative model of the lung and the insights gleaned from tissue explants are valuable, the model does not lend itself to long-term culturing and longer infection times that might be necessary to study certain aspects of mycobacterial infections.

**FUTURE PERSPECTIVES**

Historically, Mtb is humankind’s deadliest pathogen and is likely to remain a serious threat until a vaccine with high efficacy is developed; currently, the BCG vaccine provides around 50% protection on average. Difficulties in TB vaccine development might stem from a lack of knowledge about early interactions of the pathogen with the mucosal epithelia and immune players in the lung. Herein, we have attempted to provide a comprehensive overview of current research into the roles of airway and alveolar epithelium during TB infections. Far from a simple physical barrier, the epithelium in the lung appears central to directing host responses: from pathogen detection and direct killing via AMPs to the recruitment of various immune cells and antigen presentation to lymphocytes. This close interaction with the immune system might shape disease outcome in TB infections and warrants further investigation.

The covert nature of (latent) Mtb infections presents a challenge to researchers modelling early disease stages *in vitro*. Increasingly advanced cell culture systems provide promising platforms for host–Mtb research and also offer the possibility of adding other cell types or pathogens of interest in numerous combinations. The models discussed here are useful for studying early infection events and interactions between Mtb and the human host. In the future, they could be expanded to model later stages of TB disease as well. It will be of particular interest to see if granulomas can be modelled accurately, with the inclusion of EC.

In conclusion, more in-depth research regarding the role of lung epithelia during initial stages of Mtb infections is required to elucidate the complex mechanisms behind TB disease outcome. We anticipate that future studies integrating the interplay between the epithelium, immune cells and Mtb will become a new research priority in TB research.
