ABSTRACT

Rationale Acute respiratory distress syndrome (ARDS) is a lethal complication of severe bacterial pneumonia due to the inability to dampen overexuberant immune responses without compromising pathogen clearance. Both of these processes involve tissue-resident and bone marrow (BM)–recruited macrophage (MΦ) populations which can be polarised to have divergent functions. Surprisingly, despite the known immunomodulatory properties of mesenchymal stem cells (MSCs), simultaneous interactions with tissue-resident and recruited BMMΦ populations are largely unexplored.

Objectives We assessed the therapeutic use of human placental MSCs (PMSCs) in severe bacterial pneumonia with elucidation of the roles of resident alveolar MΦs (AMΦs) and BMMΦs.

Methods We developed a lethal, murine pneumonia model using intratracheal infection of a clinically relevant Klebsiella pneumoniae (KP) strain with subsequent intravenous human PMSC treatment. Pulmonary AMΦ and recruited BMMΦ analyses, histological evaluation, bacterial clearance and mice survival were assessed. To elucidate the role of resident AMΦs in improving outcome, we performed AMΦ depletion in the KP-pneumonia model with intratracheal clodronate pretreatment.

Measurements and main results Human PMSC treatment decreased tissue injury and improved survival of severe KP-pneumonia mice by decreasing the presence and function of recruited M1 BMMΦs while preserving M2 AMΦs and enhancing their antibacterial functions. Interestingly, PMSC therapy failed to rescue AMΦ-depleted mice with KP pneumonia, and PMSC-secreted IL-1β was identified as critical in increasing AMΦ antibacterial activities to significantly improve pathogen clearance—especially bacteraemia—and survival.

Conclusions Human PMSC treatment preferentially rescued resident M2 AMΦs over recruited M1 BMMΦs with overall M2 polarisation to improve KP-related ARDS survival.

INTRODUCTION

Acute respiratory distress syndrome (ARDS) is still a lethal complication of severe bacterial pneumonia, with Klebsiella pneumoniae (KP) among the most common causative agents.1 A Gram-negative bacterium with high multidrug resistance and over 80 serotypes, drug resistance and vaccine development has been difficult for KP.2,3 Among virulent KP members, the K2 serotype is the most studied since it can cause highly lethal bacterial pneumonia clinically.4 While previous reports demonstrated that augmenting the innate immune response is...
effective, both bacteraemia and overexuberant inflammation damaged multiple organs/tissues. Blockage of acute infection mediators including tumour necrosis factor (TNF-α) muted organ/tissue damage but did not improve survival, showing that careful balancing of the bactericidal immune response against excessive inflammation is critical for disease resolution. Recent clinical trials using corticosteroids—arguably the most potent anti-inflammatory agent—to mitigate excessive host responses have not consistently reduced mortality, necessitating better strategies to combat severe bacterial pneumonia or acute respiratory distress syndrome (ARDS).

Multilineage mesenchymal stem cells (MSCs) have been isolated from diverse post-natal sources including the placenta, a temporary organ with fetal contributions which is ethically compliant and easily accessible. MSC sources including placental MSCs (PMSCs) not only have regenerative properties but also strong immunomodulation with therapeutic value. Surprisingly, despite well-established interactions of MSCs with adaptive and innate immune cells like T lymphocytes and natural killer cells, respectively, reports on MSC-macrophage (MΦ) interactions are relatively scarce. Moreover, there are almost no MSC studies in which different populations of MΦs are simultaneously evaluated, despite the clear understanding currently that tissue-resident MΦs—important in maintaining tissue/organ homeostasis—are functionally and developmentally distinct from bone marrow (BM)–derived MΦs, which are among the most potent effector cells in host responses against pathogens.

The lungs, being in constant interactions with environmental pathogens and toxins, has a resident MΦ population to maintain homeostasis: the alveolar MΦ (AMΦ), derived from the yolk sac. When local infection occurs, AMΦs are the first in line to mount an immune response and recruit effector BMMΦs for effective elimination of respiratory pathogens. Both pathogen clearance and tissue damage in bacterial ARDS have been linked to MΦ activity, but the existence of two populations of MΦs during pulmonary infection—resident AMΦs and recruited BMMΦs—makes it difficult to resolve which population is responsible for tissue injury versus disease resolution. Furthermore, all MΦs can undergo functional polarisation into classically activated or M1 MΦs, crucial in fighting off invading pathogens, or alternatively activated or M2 MΦs which are important in tissue repair. An imbalance in MΦ polarisation can influence disease outcome, and AMΦs are critically involved during K2 KP infection in comparison to control/PBS-injected mice (figure 1A), with significant increases at h4 post-infection in lungs infected with an LD50 of a clinically isolated serotype K2 KP, revealing a dramatic shift in the pattern of lung-isolated MΦs at h2 versus h4 post-infection in comparison to Control/PBS-injected mice by t-SNE (figure 1C), with significant increases at h4 post-infection in a population designated G1 which is identified as CD11bhiMΦs (figure 1D–F). A population designated G2 and identified as CD11bhighMΦs was significantly decreased at h4 post-infection (figure 1E,F). These MΦ populations can be further differentiated on CD11bhigh (G1) and CD11blow (G2) expression as BMMΦs and AMΦs, respectively. Flow cytometric analyses confirmed these findings, showing an increase in the frequency as well as absolute number of BMMΦs over AMΦs at h4 (figure 1G–I). These results demonstrate that K2 KP infection rapidly decreased resident AMΦs while gradually increasing recruited BMMΦs to cause an imbalance in pulmonary MΦ populations, which possibly contribute to subsequent ARDS.

**METHODS**

A detailed description of the methods is provided in the online supplemental information.

**Cell culture**

Human PMSCs were isolated from term placental tissue obtained after institutional board approval as previously reported, and cultured as previously reported.

**Mouse model of KP-induced bacterial pneumonia and PMSC injection**

A clinical KP strain of serotype 2 was isolated from patient sputum for intratracheally inoculation into C57BL/6 mice at a sublethal or lethal dose (5×10⁶ or 5×10⁷ CFUs, respectively) according to previous report. PMSCs (3×10⁵ cells) or phosphate buffered saline (PBS) were intravenously injected 2 hours after KP injection. Mice were euthanised with CO₂ at 4 hours, with peripheral blood collected for evaluation of bacterial load and lungs collected for evaluation of bacterial load, MΦ analyses and histological evaluation.

**Assessment of in vivo MΦ function**

Single-cell suspensions derived from lung lobes were stained with antibodies recognising CD45, CD11b, F4/80, CD206, inducible nitric oxide synthase (iNOS), arginase-1 (Arg1), TNF-α (all from eBioscience, San Diego, California, USA), or 2′,7′-dichlorofluorescein diacetate (DCFDA, Sigma-Aldrich, Missouri, USA) for 30 min according to manufacturer’s instructions, then assessed by flow cytometry or analysed with t-distributed stochastic neighbor embedding (t-SNE)-based algorithm.

**In vivo depletion of AMΦs**

C57BL/6J mice were intratracheally injected with 100 μL of PBS or 15 mM clodronate (Cayman Chemical, Ann Arbor, Michigan, USA). After 48 hours, the frequency and absolute numbers of CD11bhighF4/80− AMΦs and CD11bhighF4/80− BMMΦs in lung tissues were assessed by flow cytometry.

**Statistics**

For comparisons between two groups, non-parametric Mann-Whitney test was used, while for comparisons between multiple groups, non-parametric analysis of variance was used followed by Dunn’s test. Comparisons of survival curves were made using Kaplan-Meier method with log-rank tests. A value of p<0.05 was considered statistically significant. Analyses were performed using GraphPad Prism software (California, USA), and data are shown as mean±SD.

**RESULTS**

**Pulmonary KP infection dramatically decreases resident AMΦs while increasing recruited BMMΦs in the lungs**

To assess whether MΦs are critically involved during K2 KP pneumonia, we first performed bioinformatics analysis which demonstrated broad transcriptomic changes in lung tissue from control versus KP-infected mice (figure 1A), and found MΦ-related pathways to be highly enriched (figure 1B). To further delineate immune responses at the cellular level, we performed analyses on immune cells at 2 (h2) and 4 hours (h4) in lungs infected with an LD50 of a clinically isolated serotype K2 KP, revealing a dramatic shift in the pattern of lung-isolated MΦs at h2 versus h4 post-infection in comparison to Control/PBS-injected mice by t-SNE (figure 1C), with significant increases at h4 post-infection in a population designated G1 which is identified as CD11bhiMΦs (figure 1D–F). A population designated G2 and identified as CD11bhighMΦs was significantly decreased at h4 post-infection (figure 1E,F). These MΦ populations can be further differentiated on CD11bhigh (G1) and CD11blow (G2) expression as BMMΦs and AMΦs, respectively. Flow cytometric analyses confirmed these findings, showing an increase in the frequency as well as absolute number of BMMΦs over AMΦs at h4 (figure 1G–I). These results demonstrate that K2 KP infection rapidly decreased resident AMΦs while gradually increasing recruited BMMΦs to cause an imbalance in pulmonary MΦ populations, which possibly contribute to subsequent ARDS.
Human PMSCs reduce recruitment of BMMΦs while preserving AMΦs in KP-infected lungs

To elucidate the mechanism underlying the interaction of recruited BMMΦs and resident AMΦs in KP pneumonia, we first used the Molecular Activation Prediction (MAP) tool from Ingenuity Pathway Analysis (IPA) which revealed that during pulmonary KP infection, for the process of BMMΦ migration, many inflammatory cytokines including CXCL3, CCL2 and TNF-α were involved, while for the process of AMΦ quantity, other cytokines including CSF1, CXCL17 and interleukin (IL)-36γ were highly activated (figure 2A). Among these predicted cytokines, TNF-α has been reported as critical in causing pneumonia exacerbation by several infectious agents including KP.

We therefore performed transcriptomic analyses in TNF-α-treated BMMΦs and found that multiple inflammatory pathways involving either innate or adaptive immunity were activated (figure 2B). To validate the strong presence of TNF-α during in vivo KP pneumonia and assess whether PMSC therapy could limit the highly inflammatory process represented by this cytokine, we detected TNF-α secretion in harvested lung immune cells from uninfected or KP-infected mice 2 hours post-infection which were then co-cultured ex vivo with PMSCs for another 2 hours (figure 2C). We found that PMSCs significantly decreased levels of KP-induced TNF-α even at this early time point post-infection; interestingly, this early post-infection time point is prior to recruited BMMΦs arriving in the lungs (figure 1H,I). We then further assessed PMSC interactions with both AMΦ and BMMΦ populations (figure 2D), and found both percentages (figure 2F) and absolute counts (figure 2F) of BMMΦs were significantly increased whether treated with PBS or PMSCs after KP infection, while a slight but non-significant decrease in absolute BMMΦ numbers after PMSC treatment compared with after PBS treatment in infected mice was seen. Moreover, while BMMΦ expression of CD11b—critical adhesion molecule involved in recruited BMMΦ tissue migration—was significantly increased after KP infection, PMSC but not PBS treatment resulted in a significant decrease back to nearly baseline levels (figure 2G,H). Furthermore, after KP infection, AMΦ percentages (figure 2I) were significantly decreased when only PBS was given; PMSC treatment, on the other hand, significantly rescued percentages (figure 2J). The supportive effects of PMSCs on AMΦs during KP infection were also seen when absolute cell counts were assessed (figure 2J), in which PMSC treatment nearly doubled the average number of AMΦs compared with PBS treatment. Responses of BMMΦ and AMΦ absolute numbers were further confirmed in CD11c⁺SIGLEC-F⁺ and CD11c⁺SIGLEC-F⁻ cells.
of CD11b<sup>high</sup>F4/80<sup>+</sup> and CD11b<sup>low</sup>F4/80<sup>+</sup> MΦs, respectively (online supplemental figure 1). These results suggest that PMSC administration can prevent recruitment and function of BMMΦs—likely through downregulation of KP-induced TNF-α—while significantly preserving resident AMΦs.

**Human PMSCs decrease pulmonary inflammation and tissue injury, as well as significantly increase survival of mice with KP pneumonia**

To determine PMSC therapeutic effects on bacterial clearance and tissue injury in KP pneumonia, we first assessed bacterial load and found that PMSC treatment significantly reduced bacterial numbers in infected lungs and decreased incidence of bacteremia in LD<sub>50</sub>-infected mice at 4 hours (figure 3A,B). PMSCs also significantly downregulated levels of KP-induced TNF-α within lung tissues (online supplemental figure 2), suggesting TNF-α-mediated immunity was not critical for bacterial clearance after PMSC administration. We then assessed lung tissues of uninfected and infected mice 4 hours after LD<sub>50</sub> infection histologically (figure 3C). H&E staining of lung tissue sections showed that KP infection increased immune cell infiltration (figure 3C-c), oedematous changes (figure 3C-d) and bronchial epithelium hyperplasia (figure 3C-k), which collectively indicated significant tissue injury similar to ARDS (figure 3D).

These changes were reduced (figure 3C-d,h,l) after PMSC treatment. To confirm the degree of inflammatory infiltrates, we also

**Figure 2**  Human placenta mesenchymal stem cells (PMSCs) prevent bone marrow MΦ (BMMΦ) recruitment but preserve alveolar MΦ (AMΦ) population in Klebsiella pneumoniae (KP)-infected lungs. (A) Pathway analyses of transcriptomic profiles obtained from KP-infected versus uninfected lung lobes (NCBI-GEO database: GSE121970) as performed with Molecular Activation Prediction (MAP) tool in Ingenuity Pathway Analysis (IPA), for prediction of mechanisms involved in migration of recruited BMMΦs or quantity of resident AMΦs during pulmonary KP infection. IPA showed regulatory relationships between downregulated (green) and upregulated (red) proteins; the MAP tool showed that ‘migration of BMMΦs’ and ‘quantity of AMΦs’ are upregulated (orange) through positively regulated downstream molecules (orange lines) or inconsistent findings on some mediators (yellow lines) after occurrence of KP pneumonia (red). (B) Enrichment of immune-related pathways as assessed in transcriptomic data of tumour necrosis factor (TNF)-α-treated BMMΦs versus control BMMΦs (NCBI-GEO database: GSE160163) using Metascape analysis and coloured by p values. (C) Assessment of ex vivo lung inflammation with detection of TNF-α in non-infected and KP-infected lung tissues after phosphate buffered saline (PBS) and PMSC treatment. Mice were intratracheally infected with 5×10<sup>6</sup> CFUs of K2 KP for 2 hours, and then sacrificed for extraction of lung immune cells which were ex vivo co-cultured with human PMSCs at the ratio of 10:1 for 2 hours further and supernatants collected for TNF-α detection (n=10 for each group). (D) Representative data for frequency analysis of recruited BMMΦs and resident AMΦs in lung lobes as assessed with flow cytometry. C57BL/6J mice were intratracheally injected with 5×10<sup>6</sup> CFUs of K2 KP followed by intravenous administration of PBS or 3×10<sup>5</sup> PMSCs 2 hours later. Single-cell suspensions harvested from lung tissues of non-infected mice as well as infected mice injected with PBS or PMSCs were stained with anti-CD45, anti-CD11b and anti-F4/80 for flow cytometric analysis. Gating for CD45<sup>+</sup> cells was first performed, with subsequent frequency analysis for CD11b<sup>high</sup>F4/80<sup>+</sup> BMMΦs and CD11b<sup>low</sup>F4/80<sup>+</sup> AMΦs. (E, F) Pooled data for analyses of frequency and absolute counts of recruited BMMΦs in lung lobes of each experimental group, respectively (n=8 for each group). (G, representative data; H, pooled data) Relative CD11b expression levels of recruited BMMΦs in lung lobes of each experimental group by flow cytometric analysis (n=8 for each group). (I, J) Pooled data for analyses of frequency and absolute number of resident AMΦs in lung lobes of each experimental group, respectively (n=8 for each group). Data are shown as mean±SD.
collected whole lungs of non-infected and infected mice after PBS or PMSC treatment for analysis of white blood cell (WBC) frequency and cell numbers at 4 hours post-infection. Pulmonary WBC frequency was relatively unchanged 4 hours post-infection (online supplemental figure 3A,B), but absolute numbers were significantly increased, which after PMSC administration was partially reversed (online supplemental figure 3C). To assess whether PMSCs are therapeutic for KP-induced pneumonia/ARDS, intravenously PBS or PMSCs was injected 2 hours after LD100 KP infection, and we found that PMSC administration significantly improved KP-infected mice survival rates from 0% to 42.86% (figure 3E). Collectively, these findings demonstrate that PMSC intravenous administration decreased bacterial load, local inflammation and lung tissue injury, to result in significantly improved overall survival of mice with K2 KP pneumonia.

Human PMSCs preserve resident AMΦs over BMMΦs and drive the overall milieu to an M2 immunomodulatory phenotype in mice with KP pneumonia

To assess whether PMSCs can affect polarisation of BMMΦs and/or AMΦs, we firstly analysed the functional M1 and M2 polarisation markers iNOS and Arg1, respectively. After KP infection, iNOS expression (figure 4A,B) was significantly increased but Arg1 expression (figure 4C,D) was significantly decreased in BMMΦs with PBS treatment when compared with uninfected groups; interestingly, expression of both markers was significantly reversed with PMSC treatment. For AMΦs, iNOS expression levels were similar in both uninfected and infected mice (figure 4E,F); however, Arg1 expression was slightly decreased in infected mice with PBS treatment when compared with uninfected groups although non-significantly, but could be significantly reversed with PMSC treatment (figure 4G,H).

To further delineate whether PMSCs can modulate the polarisation of both BMMΦs and AMΦs simultaneously, we firstly performed t-SNE analyses to visualise the complex changes. Concatenation of all experimental groups demonstrated that the majority of recruited BMMΦs are of the M1 phenotype (identified as CD206low), whereas the majority of resident AMΦs are of the M2 phenotype (identified as CD206high) (figure 5A). Visualisation of individual experimental groups shows that after KP infection, M1 BMMΦs were more prominent, whereas M2 AMΦs were less prominent, with PMSC treatment after KP infection rescuing M2 AMΦ presence (figure 5B). Confirmation with flow cytometric analyses (figure 5C, representative data) demonstrated that both percentages (figure 5D) and counts (figure 5E) of M1 BMMΦs treated with PBS were significantly increased from uninfected levels which were reversed by PMSC treatment. However, when compared with uninfected groups, M2 BMMΦs percentages (figure 5F) were significantly decreased to similar levels in KP-infected mice whether treated with PBS or
PMSCs, while absolute counts (figure 5G) in infected mice were significantly increased only with treatment of PMSCs but not PBS. When we turned to evaluate polarised subpopulations of AMΦs, we found that both percentages (figure 5H) and absolute counts (figure 5I) of M1 AMΦs were significantly increased from uninfected levels whether treated with PBS or PMSCs. However, PBS treatment significantly decreased M2 AMΦs percentages (figure 5J), while absolute counts (figure 5K) were similar to those in uninfected mice; PMSC treatment in infected mice, on the other hand, not only significantly reversed M2 AMΦ percentages as well as increased absolute counts compared with levels in uninfected mice. Since M1 AMΦs are also an important source of TNF-α, we next assessed whether PMSCs can modulate TNF-α expression levels in M1 subpopulation of both BMMΦs and AMΦs. We found that in uninfected mice, treatment with PBS or PMSCs did not change TNF-α levels significantly in M1 BMMΦs, while in infected mice, TNF-α levels in M1 BMMΦs was increased with PBS treatment but significantly reversed with PMSC treatment (figure 5L,M). Interestingly, there were no significant changes in TNF-α levels of M1 AMΦs between uninfected and infected mice regardless of PBS or PMSC treatment (figure 5N,O). Collectively, PMSC treatment can modulate both BMMΦs and AMΦs towards a more M2, tolerogenic response in pulmonary KP infection with particular preservation of M2 AMΦs.

Human PMSCs enhance multiple antibacterial functions in AMΦs but not BMMΦs to significantly improve bacterial clearance and survival in mice with KP pneumonia which were abrogated after AMΦ depletion

To investigate how the prominent immunomodulation of BMMΦs and AMΦs by PMSCs impact disease outcome, we first assessed two classical MΦ antibacterial functions in both MΦ populations: bacterial phagocytosis and reactive oxygen species (ROS) production. In BMMΦs, co-culture with PMSCs surprisingly decreased in vitro bacterial phagocytosis capacity significantly (figure 6A,B), while in AMΦs, PMSC co-culture significantly increased this capacity (figure 6C,D). To assess whether PMSCs can modulate the production of antibacterial effector molecules from the two MΦ populations in vivo, we measured ROS levels in AMΦs and BMMΦs harvested from lung tissues of uninfected and KP-infected mice. ROS production by BMMΦs treated with PBS or PMSCs was similar in uninfected mice, with production rising significantly after KP infection with PBS treatment which could be partially reversed when PMSCs were administered (figure 6E,F). For AMΦs, ROS production was also similar in uninfected mice treated with PBS or PMSCs, with levels significantly increased in PBS-treated infected mice, which were further increased in PMSC-treated infected mice compared with those in uninfected groups (figure 6G,H). Moreover, we concurrently assessed phagocytosis and ROS production in both M1 and M2 BMMΦs and AMΦs, and found that PMSCs suppressed both antibacterial functions in M1 BMMΦs while boosting these functions in M2 AMΦs (online supplemental figure 4). We also excluded that PMSCs have direct antibacterial properties, finding that PMSCs does not affect KP growth in vitro or virulence gene expression in vivo (online supplemental figure 5). These findings collectively demonstrate that during an active bacterial infection, PMSCs modulate BMMΦs and AMΦs in divergent directions: decreasing effector antibacterial functions in BMMΦs while increasing similar functions in AMΦs.

To assess whether PMSC preferential enhancement of AMΦ antibacterial functions was critical to improving disease outcome, we depleted AMΦs but not BMMΦs prior to KP infection using intratracheal injection of clodronate (figure 6I). In uninfected mice, intratracheal clodronate did not alter BMMΦ percentages...
or absolute counts (figure 6J,K), whereas AMΦ percentages and counts were sharply decreased (figure 6L,M), demonstrating a fivefold decrease specifically of AMΦs without affecting BMMΦs. Using this model, we then infected mice with LD50 of KP with subsequent PBS or PMSC treatment. We found that in KP-infected mice after AMΦ depletion, PMSC treatment did not significantly improve pulmonary bacterial clearance compared with PBS treatment (figure 6N). More importantly, PMSC treatment in AMΦ-depleted mice infected with sublethal KP dose not only failed to rescue mice but actually worsened the survival rate (figure 6O). These findings demonstrate that the therapeutic effects of PMSCs in severe KP pneumonia were dependent on AMΦs and their antibacterial capacities.

Figure 5 Human placental mesenchymal stem cells (PMSCs) reduce the population and function of M1 bone marrow MΦs (BMMΦs) while preserving M2 alveolar MΦs (AMΦs) in mice with Klebsiella pneumoniae (KP) pneumonia. (A, pooled data; B, representative data) Population analyses for M1 and M2 BMMΦs as well as M1 and M2 AMΦs with PhenoGraft on the MΦ-based t-distributed stochastic neighbor embedding (t-SNE) map. Single-cell suspensions harvested from lung tissues stained with phosphate buffered saline (PBS) or PMSCs were stained with anti-CD45, anti-CD11b, anti-F4/80 and anti-CD206, assessed by flow cytometry and analysed with t-SNE-based algorithm. Gating for CD45+CD11bhighF4/80+ M1 BMMΦs and CD206+CD11bhighF4/80+ M1 AMΦs as well as CD206CD11bhighF4/80+ M2 BMMΦs as well as CD206CD11bhighF4/80+ M1 AMΦs and CD206CD11bhighF4/80+ M2 AMΦs were gated on the two t-SNE dimensions. (C) Representative data for frequency analyses of M1 and M2 populations in BMMΦs or AMΦs from lung lobes as assessed with flow cytometry. Gating for CD45+CD11bhighF4/80+ M1 BMMΦs was first performed, with subsequent analyses for CD11b and CD206 signals. (D, E) Pooled data for analyses of frequency and absolute number, respectively, of CD45+CD11bhighF4/80+ M1 BMMΦs (n=10 for each group). (F, G) Pooled data for analyses of frequency and absolute number, respectively, of CD206CD11bhighF4/80+ M2 BMMΦs (n=10 for each group). (H, I) Pooled data for analyses of frequency and absolute number, respectively, of CD206CD11bhighF4/80+ M1 AMΦs (n=10 for each group). (J, K) Pooled data for analyses of frequency and absolute number, respectively, of CD206CD11bhighF4/80+ M2 AMΦs (n=10 for each group). (L, M) Representative data for frequency analyses of M1 and M2 populations in BMMΦs or AMΦs from lung lobes as assessed with flow cytometry. Gating for CD45+CD11blowF4/80+ M1 AMΦs as assessed in CD45+CD11blowF4/80+ CD206+ single-cell suspensions harvested from lung tissues, followed by intracellular staining of tumour necrosis factor (TNF)-α (n=10 for each group). (N, O) Pooled data for TNF-α expression levels of M1 AMΦs as assessed in CD45+CD11blowF4/80+ CD206+ single-cell suspensions harvested from lung tissues, followed by intracellular staining of TNF-α (n=10 for each group). Data are shown as mean±SD.
**Figure 6** Human placental mesenchymal stem cells (PMSCs) enhanced multiple antibacterial functions in alveolar MΦs (AMΦs) but not bone marrow MΦs (BMMΦs) to significantly improve bacterial clearance and survival in mice with *Klebsiella pneumoniae* (KP) pneumonia which were abrogated after AMΦ depletion. (A, representative data; B, pooled data) The capability of KP phagocytosis in BMMΦs harvested from lung tissues co-cultured in phosphate buffered saline (PBS) or with PMSCs (n=10 for each group) for 2 hours as assessed with subsequent addition of FITC-labelled KP for 30 min at 37°C. Phagocytic capability of BMMΦs was measured by detecting for the frequency of FITC+ cells in CD11bhighF4/80+. (C, representative data; D, pooled data) The capability of KP phagocytosis in AMΦs harvested from lung tissues co-cultured in PBS or with PMSCs (n=10 for each group) for 2 hours as assessed with subsequent addition of FITC-labelled KP for 30 min at 37°C. Phagocytic capability of AMΦs was measured by detecting for the frequency of FITC+ cells in CD11bhighF4/80+. (E, representative data; F, pooled data) Assessment of AMΦ respiratory burst as measured by reactive oxygen species (ROS) production of H₂O₂ in each experimental group. Isolated cells from lung tissues were incubated with 10µM of 2′,7′-dichlorofluorescein diacetate (DCFDA) for 30 min, and then analysed by flow cytometry to assess ROS levels in CD45+CD11bhighF4/80+ BMMΦs (n=8 for each group). (G, representative data; H, pooled data) Assessment of AMΦ respiratory burst as measured by ROS production of H₂O₂ in each experimental group. Isolated cells from lung tissues were incubated with 10µM DCFDA for 30 min, and then analysed by flow cytometry to assess ROS levels in CD45+CD11bhighF4/80+ BMMΦs (n=8 for each group). (I) Representative data for frequency analyses of CD11bhighF4/80+ BMMΦs and CD11bhighF4/80+ AMΦs in lung lobes treated with PBS or clodronate as assessed with flow cytometry. C57BL/6J mice were intratracheally injected with 100 µL of PBS or 15 mM clodronate solution. After 2 days, single-cell suspensions harvested from lung tissues were stained with anti-CD45, anti-CD11b and anti-F4/80 for flow cytometric analyses. Gating for CD45+ cells was first performed, with subsequent frequency analysis for CD11bhighF4/80+ BMMΦs and CD11bhighF4/80+ AMΦs, respectively (n=6 for each group). (J, K) Pooled data for analyses of frequency and absolute number of CD11bhighF4/80+ BMMΦs and CD11bhighF4/80+ AMΦs, respectively (n=6 for each group). (L) Assessment of bacterial load within lung homogenate in clodronate-pretreated mice infected with 5×10⁸ CFU of K2 KP. Clodronate-pretreated mice were then intratracheally infected with sublethal dose (5×10⁶ CFU) of K2 KP followed by intravenous administration of PBS or 3×10⁵ PMSCs 2 hours later. Lung lobes were collected for detection of bacterial burden (n=6 for each group). (O) Kaplan-Meier survival analysis of clodronate-pretreated/AMΦ-depleted mice with K2 KP infection (5×10⁶ CFU) after PBS or PMSC treatment. Survival was observed for 12 days (n=8 for each group). Data are shown as mean±SD.

**Human PMSC-secreted IL-1β prominently increase AMΦ antibacterial functions to significantly improve KP pneumonia disease outcome**

To identify which factor may be involved in the potent capacity of PMSCs to modulate and significantly increase multiple AMΦ antibacterial functions, we performed transcriptome profiling of PMSCs and MAP analysis, finding IL1B to be the most potential candidate (figure 7A). To ascertain whether IL-1β is responsible for PMSC-mediated enhancement of AMΦ antibacterial functions, we assessed both in vitro KP phagocytosis and in vivo ROS production of AMΦs under KP infection with subsequent treatment of PMSCs after specific knockdown of IL1B (shIL1B-PMSCs) or non-target knockdown (shLuc-PMSCs). Compared with PBS group, co-culture with shLuc-PMSCs significantly increased AMΦ in vitro bacterial phagocytic capacity while co-culture with shIL1B-PMSCs reversed the capacity back to baseline (figure 7B–C). ROS production in AMΦs of KP-infected mice was significantly increased with shLuc-PMSC treatment, but not with shIL1B-PMSC treatment which resulted in levels close to PBS-treated levels (figure 7D,E). To determine whether PMSC-expressed IL-1β was critical to improving disease outcome, we first assessed bacterial clearance in KP-infected mice 4 hours post-infection. We found that the local pulmonary bacteria load in KP-infected mice after PBS treatment was significantly increased than that in infected mice treated with shLuc-PMSCs (figure 7F). However, in KP-infected mice treated with...
shL1B-PMSCs, a significantly higher bacterial load was seen when compared with levels in shLuc-PMSC-injected infected mice. The importance of PMSC-secreted IL-1β was even more prominent in reducing systemic bacterial load (figure 7G). Most importantly, treatment of shLuc-PMSCs but not shL1B-PMSCs significantly improved survival of LD90-infected mice (figure 7H). These findings demonstrate the importance of IL-1β in PMSC modulation of AMΦs to improve disease outcomes of severe bacterial pneumonia/ARDS.

DISCUSSION

The lungs are in constant contact with the environment, thus requiring resident AMΦs to maintain immune homeostasis and tissue repair, and during infections, recruited BMMΦs require resident AMΦs to maintain immune homeostasis.17 The caref ul orchestration in the actions of these two MΦ populations during severe bacterial infections is crucial not only for pathogen clearance but also limiting the concomitant, potentially lethal tissue injury. Thus, it is surprising that no previous reports have evaluated MSC interactions towards AMΦs and BMMΦs simultaneously, especially since MSC therapy appear particularly suited for pulmonary diseases given the tremendous first-pass effect with intravenous delivery, effects which are further increased with inflammation.10 31 Surprisingly, many studies of MSCs for bacterial pulmonary infections have used less clinically relevant models such as applying lipopolysaccharide (LPS) only or Escherichia coli, given MSCs intratracheally, or not evaluated survival.32-33 Two reports have used more clinically relevant bacteria, such as Streptococcus pneumoniae but not evaluating MΦs in vivo,34 and another used KP but treated with murine BMMSCs intratracheally;17 neither reports studied resident AMΦs. Two other reports evaluated MSC-pulmonary MΦ interactions using E. coli, and found that MSCs reduced overall pulmonary MΦ inflammatory responses including enhancing bacterial phagocytosis.18 19 However, the study did not ascertain whether the isolated pulmonary MΦs from infected lungs were truly AMΦs. MSC-CD11blow MΦ interactions have been evaluated in one early study, finding that MSC-derived medium can modulate these MΦs to an M2 phenotype after in vitro LPS stimulation.40 Despite considerable differences in methodology and endpoints, findings collectively from these earlier studies are surprisingly similar to our more detailed investigation of MΦ subpopulations and specific roles: during pulmonary inflammation/infection, MSCs modulate MΦ populations towards an immunomodulatory M2 phenotype to decrease overexuberant inflammatory responses while enhancing antibacterial functions.
to significantly improve tissue repair and disease outcome. Our study demonstrates that PMSC-secreted IL-1β, the endogenous pyrogen highly produced by innate immune cells in response to infection, is critical in mediating survival benefits against severe KP pneumonia and complications. Generally considered to be immunomodulatory rather than inflammatory, PMSC production of IL-1β is unexpected, but may make sense teleologically. The placenta has few effector-phenotype immune cell populations, and it is plausible that non-immune cells such as PMSCs ‘take over’ these functions, although at a much less vigorous level, as the amount of IL-1β expressed by PMSCs is very low compared with levels in bacterial infection (data not shown). Further research is warranted to explore whether PMSCs have source-specific immunomodulatory properties.

Overall, we demonstrate that human PMSCs differentially modulate resident AMΦs and recruit BMMΦ in severe KP pneumonia to minimize tissue injury and improve disease outcome, with the overall immune milieu shifted towards an M2, immunomodulatory phenotype. Specifically, PMSC-secreted IL-1β increases AMΦ antibacterial functions and is critical in improving pathogen clearance especially systemic bacteraemia, and survival (figure 7J). These findings demonstrate the distinct roles of MΦ populations in infection and recovery, as well as strongly implicate a potential therapeutic role for PMSCs in severe bacterial pneumonia/ARDS.

SUPPLEMENTAL INFORMATION

SUPPLEMENTARY METHODS

Cell culture

Human PMSCs were isolated as previously reported. Term placental tissue (38–40 weeks gestation) were obtained from healthy donor mothers after obtaining informed consent approval as reviewed by the institutional review board. PMSCs were cultured in low-glucose DMEM (Invitrogen-Thermo Fisher Scientific, MA, USA), with 10% FBS (Hyclone-Thermo Fisher Scientific), 100 U/ml penicillin, 100 g/ml streptomycin and 2 mM L-glutamine (all from Gibco-Thermo Fisher Scientific).1, 2

Mouse model of KP-induced bacterial pneumonia and PMSC injection

A clinical KP strain of serotype 2 was isolated from sputum. The strain was grown in 20 ml of LB broth (Alpha Biosciences, Baltimore, MD, USA) at 37°C on a shaker at 200 rpm. After overnight incubation, bacteria were then cultured in a 1:5 dilution for additional 4 hours at 37°C until an optical density of 0.9 at 600nm was reached to ascertain bacterial counts of 4 x 10^8 colony-forming units (CFUs)/ml. Bacteria were then diluted in sterile PBS to a sublethal dose (5x10^6 CFUs/50 μl) or lethal dose (5x10^7 CFUs/50 μl) for intratracheal (i.t.) inoculation and maintained on ice until inoculation. Bacterial pneumonia was conducted in mice according to previous report. Using protocols approved by the Institutional Animal Care and Use
Committee, 6-week old C57BL/6 mice were anesthetized with intraperitoneal a Zoletil/Xylazine mixture (Zoletil: 20-40 mg/kg, Xylazine: 5-10 mg/kg, both from Sigma-Aldrich), and then inoculated intratracheally with 50 μl of the KP suspension. Appropriate dilutions of the inoculum were plated on LB agar plates to confirm the dose administered. Control group of mice were inoculated with 50 μl of PBS. PMSCs (3 x 10^5 cells in 100μl) or PBS were intravenously injected 2 hours after KP injection. Mice were euthanized with CO_2 at 4 hours, with peripheral blood collected for evaluation of bacterial load and lungs collected for evaluation of bacterial load, MΦ analyses, TNF-α detection, and histological evaluation.

**Enzyme-linked immunosorbent assay (ELISA)**

Lung-infiltrated immune cells were harvested after mice were infected with or without K2 KP for 2 hours, and then cultured in the presence or absence of PMSCs ex vivo for 2 hours additionally, with supernatant collected for TNF-α detection by ELISA according to manufacturer’s instructions (eBioscience Systems).

**Histological analysis**

Lung lobes were excised and then fixed with 10% formalin overnight. Fixed lung lobes were sequentially dehydrated with 20% and 30% sucrose, then subsequently embedded in optical cutting temperature compound (OCT), followed by sectioning (10 μm thick) and H&E staining. The scoring of lung tissue injury was performed by a different technician, and done
according to a previous report⁶ in which interstitial damage, vasculitis, peri-bronchitis, edema, thrombus formation, and pleuritic were all evaluated—this evaluation then resulted in a score of 0 for normal/no injury, 1 = mild injury, 2 = moderate injury, 3 = severe injury, and 4 = very severe injury.

Assessment of in vivo MΦ function

Lung lobes were minced with scissors to 1mm-sized chunks and dissected with 50 U/ml DNase and 1 mg/ml type IV collagenase at 37°C for 30 minutes. An equal volume of heat inactivated FBS was added to stop the enzymatic reaction. Single-cell suspensions were harvested by filtering through 100 μm strainer, lysing red blood cells in hypotonic buffer (H₂O with 0.15 M NH₄Cl, 10 mM KHCO₃ and 0.1 mM Na₂-EDTA) and washing with cold PBS. Then, the single-cell suspensions derived from lung lobes were stained with APC- or APC-Cy7-anti-mouse CD45, PerCP-anti-mouse CD11b, FITC- or PE-anti-mouse F4/80, APC- or FITC-anti-mouse CD206, PE-anti-mouse inducible nitric oxide synthase (iNOS), APC-anti-mouse arginase-1 (Arg1), PE-Cy7-anti-mouse TNF-α (all from eBioscience, San Diego, CA, USA), or FITC-anti-mouse CD11c, PE-Cy7-anti-mouse SIGLEC-F, 2′-7′-dichlorofluoresceindiacetate (DCFDA, Sigma-Aldrich, MO, USA) for 30 minutes according to manufacturer’s instructions, then assessed by flow cytometry or analyzed with t-Distributed Stochastic Neighbor Embedding (t-SNE)-based algorithm. CD45 was first gated for analysis of the frequency of CD11b<sup>low</sup>F4/80<sup>+</sup> AMΦs and CD11b<sup>high</sup>F4/80<sup>+</sup> BMMΦs, and then either iNOS and Arg1, or CD206, TNF-α,
CD11c and SIGLEC-F were analyzed for the polarization phenotypes and further confirmation of both MΦs. Reactive oxygen species (ROS) production was assessed in gated AMΦs and BMMΦs by flow cytometry.

**In vivo depletion of AMΦs**

C57BL/6J mice were intratracheally injected with 100 μl of PBS or 15mM clodronate (Cayman Chemical, Ann Arbor, MI, USA). After 48 hours, the frequency as well as absolute numbers of CD11b<sup>low</sup>F4/80<sup>+</sup> AMΦs and CD11b<sup>high</sup>F4/80<sup>+</sup> BMMΦs in lung tissues were assessed by flow cytometry. The efficacy for AMΦ depletion with clodronate was similar to use of liposomal clodronate at 3 days (data not shown), in line with previous report.

**Bacterial phagocytosis assay**

Lung lobes from non-infected mice were harvested in RPMI (Invitrogen-Thermo Fisher Scientific)-based culture medium with 10% FBS, 100 U/ml penicillin, 100 g/ml streptomycin and 2 mM L-glutamine after animal euthanasia with CO<sub>2</sub>, washed with PBS and placed in petri dishes with 0.5 ml PBS. The lung tissues were minced with scissors to 1mm-sized chunks and dissected with 50 U/ml DNase and 1 mg/ml type IV collagenase at 37°C for 30 minutes. An equal volume of culture medium was added to stop the digestion reaction. Extracted cells were harvested by filtering with a 100 μm strainer, and red blood cells were lysed in hypotonic buffer (H<sub>2</sub>O with 0.15 M NH₄Cl, 10 mM KHCO<sub>3</sub>and 0.1 mM Na<sub>2</sub>-EDTA, all components from Sigma-
Aldrich) and washed with cold PBS. Immune cells harvested from lung tissues were cultured with PMSCs for 2 hours, and then exposure to FITC-labeled *KP* at 37°C for 30 minutes.

Suspended cells were collected and washed with cold PBS and then stained with APC-anti-mouse CD45, PerCP-anti-mouse CD11b, PE-anti-mouse F4/80. After further washing with PBS and fixing with 1% formaldehyde, CD45-gated cells were analyzed for the frequency of *KP* uptake in CD11b<sub>low</sub>F4/80<sup>+</sup> AMΦs and CD11b<sub>high</sub>F4/80<sup>+</sup> BMMΦs by flow cytometry.

**Bacterial growth assay**

*KP* growth was performed as we previously reported. Briefly, *KP* suspensions were cultured for 2 hours and then measured by calculating colony-forming unit (CFU) in the presence or absence of PMSCs. 5 x 10<sup>5</sup> CFUs of live *KP* suspensions were added to culture medium or 2 x 10<sup>4</sup> PMSCs for 2-hour incubation, and then culture samples were serially diluted with PBS and plated on agar plates for calculation of bacterial counts.

**Determination of in vivo bacterial dissemination**

Lung lobes were harvested in 0.5ml cold PBS after animal euthanasia with CO₂, and then fragmented with scissors and homogenized with syringes. Aliquots from lungs and blood samples were diluted with cold PBS and plated on LB agar plates (Alpha Biosciences) at 37°C. After overnight incubation, CFUs were calculated.
**Determination of in vivo expression of bacterial virulence genes**

Mice were i.t. injected with a 5x10⁶ CFUs of K2 KP followed by i.v. administration of PBS or 3x10⁵ PMSCs 2 hours later. At 4 hours after infection, lung lobes were excised, homogenized, serial diluted with PBS, and plated on agar plates for overnight culture. Finally, single colony derived from each animal sample was picked up for PCR analyses. KP virulence genes including regulator of mucoid phenotype A (rmpA), activator for capsular polysaccharide synthesis (rmpA2), enterobactin synthase component B (entB) and last universal common ancestor (LUCA) as internal control were evaluated according to our previous report.⁹

**RNA silencing**

The lentiviral system for IL1B knockdown was obtained from the Taiwan National RNAi Core Facility (Sinica, Taipei, Taiwan). To generate lentiviruses carrying short hairpin RNA (shRNA), we co-transfected pLKO.1-shLuc (negative control; target sequence, 5’-CGGTTGCCAGAGGTTCAT-3’) or pLKO.1-shIL1B (target sequence, 5’-CGGCCAGGAATAATACGTCTT-3’) with packaging vectors, pCMVdelR8.91 and pMD.G, into 293T cells according to protocols provided by the Taiwan National RNAi Core Facility. To knockdown IL1B expression, PMSCs were infected with 10 RIU/cell of prepared lentiviruses in the presence of 8 μg/ml protamine sulfate (Sigma-Aldrich).⁸ After 24 hours of infection, the viral medium was replaced with 2 μg/ml puromycin (Sigma-Aldrich)-containing culture medium and cultured for 2 days, with the surviving cells used for experimentation.
Bioinformatic analyses

Transcriptomic profiling databases were obtained from the National Center for Biotechnology Information-Gene Expression Omnibus database for bioinformatic analyses: GSE121970 generated from lung tissues of control mice or K2 KP-infected mice,\textsuperscript{10} and GSE160163 generated from murine BMMΦs treated with or without TNF-α.\textsuperscript{11} Principal component analysis (PCA) of transcriptomic profiles was performed to show the relatedness of whole transcriptomic profiles between control and KP-infected lung tissues using Partek® Flow\textsuperscript{®} software (Partek, Inc., St. Louis, MO), while MΦ- or immune-related pathways in Gene Ontology (GO) Biological Processes were enriched by Metascape analysis; significance was set at $P < 0.01.\textsuperscript{12}$ The Molecular Activation Prediction (MAP) tool was used to interrogate networks and pathways with expression levels of involved genes by analyzing transcriptomic data of lung tissues in KP-infected mice versus control mice using Ingenuity Systems Pathway Analysis (IPA) software (QIAGEN, Hilden, Germany).

Figure S1

Supplementary Figure 1. Human placenta mesenchymal stem cells (PMSCs) prevent CD11b\textsuperscript{high}F4/80\textsuperscript{+} or CD11b\textsuperscript{high}F4/80\textsuperscript{+}CD11c\textsuperscript{−}SIGLEC-F\textsuperscript{−} bone marrow-derived macrophages (BMMΦs) but preserve CD11b\textsuperscript{low}F4/80\textsuperscript{+} or CD11b\textsuperscript{low}F4/80\textsuperscript{+}CD11c\textsuperscript{+}SIGLEC-F\textsuperscript{+} alveolar macrophages (AMΦs) in KP-infected lungs. (A) Representative data for frequency analysis of recruited BMMΦs and resident AMΦs in lung lobes as assessed with flow cytometry. C57BL/6J mice were intratracheally (i.t.) injected with 5x10\textsuperscript{6} CFUs of K2 KP followed by intravenous (i.v.) administration of PBS or 3x10\textsuperscript{5} PMSCs 2 hours later. Single-cell suspensions derived from lung lobes were harvested at 4 hours after infection, and then stained with anti-CD45, anti-CD11b, anti-F4/80, anti-CD11c, and anti-SIGLEC-F for flow cytometric analysis. Gating for CD45\textsuperscript{+} cells was first performed, with subsequent frequency analysis for
CD11b\textsuperscript{high}F4/80\textsuperscript{+} BMMΦs and then the CD11c\textsuperscript{−} SIGLEC-F\textsuperscript{−} population, as well as CD11b\textsuperscript{low}F4/80\textsuperscript{+} AMΦs and then the CD11c\textsuperscript{+} SIGLEC-F\textsuperscript{+} population. Isotype control antibodies related to all used antibodies were mixed to serve as a control for each gating protocol. (B and C) Pooled data for analyses of absolute counts of CD11b\textsuperscript{high}F4/80\textsuperscript{+} BMMΦs and CD11b\textsuperscript{low}F4/80\textsuperscript{+} AMΦs, respectively, in uninfected and infected lungs with or without PMSC treatment (n = 8 for each group). (D and E) Pooled data for analyses of absolute counts of CD11b\textsuperscript{high}F4/80\textsuperscript{+} CD11c\textsuperscript{−} SIGLEC-F BMMΦs and CD11b\textsuperscript{low}F4/80\textsuperscript{+} CD11c\textsuperscript{+} SIGLEC-F AMΦs, respectively, in uninfected and infected lungs with or without PMSC treatment (n = 8 for each group). Data are shown as mean ± SD.
Supplementary Figure 2. Human PMSCs decrease levels of secreted TNF-α in KP-infected lungs. Mice were i.t. infected with 5x10⁶ CFUs of K2 KP followed by i.v. administration of PBS or 3x10⁵ PMSCs 2 hours later. At 4 hours after infection, mice were sacrificed and lung tissues were collected for homogenization for assessment of TNF-α by ELISA (n = 8 for each group).
Figure S3

Supplementary Figure 3. Human PMSCs decrease the pulmonary infiltration of white blood cells (WBCs) in mice with pneumonia induced by clinically isolated *Klebsiella pneumonia* (K2). (A & B, n=8 for each group) Representative and pooled data, respectively, of frequency of WBCs in lung lobes of each experimental group as assessed by flow cytometry. Gating for CD45+ cells was performed and analyzed for frequency. (C, n=3, 3, 5, 5) Absolute number of WBCs in lung lobes of each experimental group as assessed by flow cytometry with gating for CD45+ cells. Data are shown as mean ± SD.
Supplementary Figure 4. Human PMSCs downregulate capabilities of phagocytosis and respiratory burst in M1-type BMMΦs while upregulating these antibacterial functions in M2-based AMΦs in mice with KP pneumonia. (A and B) Capabilities of KP phagocytosis in M1 and M2 BMMΦs harvested from lung tissues co-cultured with or without PMSCs for 2 hours as assessed with subsequent addition of FITC-labeled KP for 30 minutes at 37°C.

Phagocytic capabilities of M1 and M2 BMMΦs were measured by detecting for the frequency of FITC+ cells in CD45+CD11bhighF4/80−CD206− and CD45+CD11bhighF4/80−CD206+, respectively (n = 8 for each group). (C and D) Assessment of M1 and M2 BMMΦ respiratory burst as measured by reactive oxygen species (ROS) production of H2O2. Single-cell suspensions derived from lung tissues were incubated with 10 μM of 2′-7′-dichlorofluoresceindiacetate (DCFDA) for 30 minutes, and then analyzed by flow cytometry to assess ROS levels in
CD45\(^+\)CD11\(^{\text{high}}\)F4/80\(^{-}\)CD206\(^-\) and CD45\(^+\)CD11\(^{\text{high}}\)F4/80\(^{-}\)CD206\(^-\) BMMΦs (n = 8 for each group). (E and F) Capabilities of KP phagocytosis in M1 and M2 AMΦs derived from lung tissues co-cultured with or without PMSCs for 2 hours as assessed with subsequent addition of FITC-labeled KP for 30 minutes at 37\(^\circ\)C. Phagocytic capabilities of M1 and M2 AMΦs were measured by detecting for the frequency of FITC\(^+\) cells in CD45\(^+\)CD11\(^{\text{low}}\)F4/80\(^{-}\)CD206\(^-\) and CD45\(^+\)CD11\(^{\text{low}}\)F4/80\(^{-}\)CD206\(^+\), respectively (n = 8 for each group). (G and H) Assessment of M1 and M2 AMΦ respiratory burst as measured by ROS production of H\(_2\)O\(_2\). Single-cell suspensions derived from lung tissues were incubated with 10 \(\mu\)M of DCFDA for 30 minutes, and then analyzed by flow cytometry to assess ROS levels in CD45\(^+\)CD11\(^{\text{low}}\)F4/80\(^{-}\)CD206\(^-\) and CD45\(^+\)CD11\(^{\text{low}}\)F4/80\(^{-}\)CD206\(^+\) AMΦs (n = 8 for each group).
Figure S5

Supplementary Figure 5. Human PMSCs negligibly affect the virulence of KP. (A) KP growth as assessed by measurement of colony-forming unit (CFU) in the presence or absence of PMSCs. 5 x 10^5 CFUs of live KP suspension were added to culture medium or 2 x 10^4 PMSCs for 2-hour incubation, and then culture samples were serially diluted with PBS and plated on agar plates for calculation of bacterial counts. (B) PCR analyses of KP virulence genes including regulator of mucoid phenotype A (rmpA), activator for capsular polysaccharide synthesis (rmpA2), enterobactin synthase component B (entB), with last universal common ancestor (LUCA) as internal control. Mice were i.t. injected with a 5x10^6 CFUs of K2 KP followed by i.v. administration of PBS or 3x10^5 PMSCs 2 hours later. At 4 hours after infection, lung lobes were excised, homogenized, serial diluted with PBS, and plated on agar plates for overnight culture. Finally, single colony derived from each animal sample was picked up for PCR analyses.
